Physiological ba

PREFACE TO FIRST EDITION

Physiology is a science in its own right and the laboratory worker who pursues his researches quite detached from medical problems need offer no apology for his academic outlook. Indeed some of the most valuable contributions to medical science have been the outcome of laboratory studies whose applications could not have been foreseen. Nevertheless, we feel that the teacher of physiology in a medical school owes it to his students, whose ultimate interest it must be conceded is in the diagnosis and treatment of disease, to emphasize those aspects of the subject which will throw light upon disorders of function. The physiologist can in this way play a part in giving the student and practitioner a vantage point from which he may gain a rational view of pathological processes.

We have endeavored to write a book which will serve to link the laboratory and the clinic, and which will therefore promote continuity of physiological teaching throughout the pre-clinical and clinical years of the under-graduate course. It is also hoped that when the principles underlying diseased states are pointed out to the medical student, and he is shown how a knowledge of such principles aids in the interpretation of symptoms or in directing treatment, he will take a keener interest in physiological studies. When such studies are restricted to the classical aspects of the subject, apparently remote from clinical application, the student is likely to regard them only as a task which his teachers in their inscrutable wisdom have condemned him to perform. Too often he gains the idea, from such a course, that physiology is of very limited utility and comes to believe that, having once passed into the clinical years, most of what he has "crammed" for examination purposes may be forgotten without detriment to his more purely medical studies. Unfortunately, he does not always realize at this stage in his education how great has been the part which physiological discoveries have played in the progress of medicine, and that the practice of today has evolved from the "theories" of yesterday.

Many physiological problems can be approached only through animal experimentation. Advances in many fields, most notably in those of carbohydrate metabolism, nutrition, and endocrinology, bear witness to the fertility of this method of research. On the other hand, many problems can be elucidated only by observations upon man, and physiology has gained much from clinical research. The normal human subject as an experimental animal possesses unique advantages for many types of investigation; and in disease, nature produces abnormalities of structure and function which the physiological laboratory can imitate only in the crudest way. Within recent years the clinical physiologist, fully realizing these advantages and the opportunities afforded by the hospital wards, has contributed very largely to physiological knowledge. In many instances, clinical research has not only revealed the true nature of the underlying process in disease, but has cast a light into some dark corner of physiology as well; several examples of clinical investigation which have pointed the way to the physiologist could be cited. In the last century, knowledge of the processes of disease was sought mainly in studies of morbid *anatomy*; biochemistry was in its infancy and many of the procedures now commonly employed for the investigation of the human subject had not been devised. Today, the student of scientific medicine is directing his attention more and more to the study of morbid *physiology* in his efforts to solve clinical problems. This newer outlook has borne fruit in many fields. It has had the beneficent result of drawing the clinic and the

physiological and biochemical laboratories onto common ground from which it has often been possible to launch a joint attack upon disease. We feel that this modern trend in the field of research should be reflected in the teaching of medical students, and have therefore given greater prominence to clinical aspects of the subject than is usual in physiological texts.

In order to understand the function of an organ it is usually essential to have a knowledge of its structure. For this reason we have followed the plan of preceding the account of the physiology of a part by a short description of its morphology and, in many instances, of its nerve and blood supply. The architecture and functions of the central nervous system are so intimately related that some space has been devoted to a description of the more important fiber tracts and grey masses of the cerebrum, cerebellum and spinal cord.

We wish to thank our colleagues in physiology, biochemistry and anatomy whom we have drawn upon on so many occasions for information and advice; without their generous help the undertaking would have been an almost impossible one. We are also deeply grateful for the unstinted assistance which we have received from our friends on the clinical staff, several of whom have read parts of the text in manuscript or in proof. We wish especially to acknowledge our indebtedness to Professor A. M. Wynne, who has written the section on the oxidizing systems of living cells, to Dr. J. K. W. Ferguson for his collaboration in the preparation of Chapter XXXIII, and to Professor C. B. Weld and Dr. E. T. Waters whose stimulating criticisms and sound counsel have been invaluable.

Finally, we wish to thank our secretaries, Miss Mabel Cory and Miss Dudley Martin, who have spent so many tedious hours in preparing the manuscript for the press, in checking the references and in compiling the index.

PREFACE TO THE FOURTH EDITION

This book, in its fourth edition, has taken on a new form and dress which the authors feel sure will be welcomed by the student. The two-column format has necessitated an entire resetting of type and along with this as much proof-reading, indexing and correcting as is required in a first edition—and incidentally, with little doubt, as many uncorrected errors. Besides saving space, the reader will find that the double-column page makes for much easier reading, more of the subject is before his eyes at the moment and his mind will be less distracted by the turning of pages. The majority of the figures have been reduced to one column width thus permitting a further saving of space, with little, if any, loss of clearness. A number of new figures have been added, others have been replaced or improved by re-drawing. There has been no abridgement of the text: new material in excess of deletions, has actually resulted in a considerable extension.

Dr. Wynne has rewritten his section entitled *Intracellular oxidation and the biological transformation of energy*. We cordially offer him our thanks. We also wish to thank again Miss Mabel Corey for her invaluable secretarial assistance.

SECTION I. THE BLOOD AND LYMPH

CHAPTER I

THE PHYSIOLOGICAL PROPERTIES, PHYSICAL CHARACTERS AND COMPOSITION OF THE BLOOD

OUTLINE OF THE FUNCTIONS OF BLOOD

In animals whose bodies are composed of many cells (the metazoa) the blood serves those purposes which, for unicellular organisms (the protozoa) are carried out by the fluid medium, the salt or fresh water, which surrounds them and bathes their surfaces. For instance, an organism such as the amoeba acquires oxygen by diffusion directly from the environment into the interior of the cell. Similarly the carbon dioxide diffuses outwards. The processes of nutrition and the excretion of the products of the cell's metabolism are accomplished in a manner equally simple. Food is taken in through the cell membrane either in solution or as particulate matter, and waste products pass into the surrounding medium. Other requirements of this organism, such as the maintenance of an optimum temperature and the proper degree of moisture, are dependent on the immediate environment.

The elemental needs of each cell in a multicellular form from the most primitive type to the highest vertebrate are the same as for the unicellular organism; yet in the evolution of the higher forms the cells composing their bodies have become farther and farther removed from immediate contact with the outside world. Myriads of cells have become packed together, and the deeper ones could not possibly satisfy their needs after the direct and simple fashion of the unicellular forms. The more primitive multicellular types overcame the difficulty by the development of canal systems which opened upon their exteriors and through which the ocean waters flowed freely in and out, bringing oxygen and aliment to the more deeply lying cell and bearing carbon dioxide and other excretory products away. This, the first attempt at a circulation, was an open one. As higher forms evolved the circulation became closed and the waters of the environment no longer flowed and ebbed through the body. No longer could the interchange of the respiratory gases and the absorption of nutriment be carried out in this direct and simple way. Yet the vessels of this closed circu-

latory system were filled with a fluid which took the place of and fulfilled the duties of the watery environment of the more primitive types. The blood and other body fluids may be looked upon as that environment which has become enclosed within the bodies of the higher forms, and has undergone certain modifications in its composition to meet the requirements of the more specialized cells which it bathes.

The similarity between the compositions of sea water and blood which has been stressed by the researches of Macallum lends support to these views on the evolution of the blood.¹ This brief account will also serve as an introduction to a consideration of the functions of the body fluids, since their duties are to satisfy in the same way as did their prototype, the requirements of the individual cells.

(1) *Respiratory.* The transport of oxygen from the air in the lungs to the tissues, and of carbon dioxide from the tissues to the lungs.

(2) *Nutritive.* The conveyance of food materials, glucose, amino acids and fats from the alimentary canal to the tissues.

(3) *Excretory.* The removal of waste products of metabolism, e.g., urea, uric acid, creatinine, etc.

(4) *The maintenance of the water content of the tissues.* Though the blood itself is contained within vascular channels a constant interchange of fluid through the vessel walls takes place. This fluid which has left the blood vessels and come into direct contact with the tissue cells is known as the lymph, or tissue juice. It closely resembles the blood fluid in chemical composition. Through the medium of the transuded fluid the final stage in the transportation of oxygen and food materials to the tissues and the first stage in the journey of CO₂ and waste products from the tissues are made. It is the very high solvent and ionizing powers of water of which the blood fluid and lymph are chiefly constituted (p. 2) which render these such admirable

¹ Sea water of today differs from blood serum in having a total salt concentration of about 3 per cent, a much higher concentration of magnesium and a lower concentration of potassium. But Macallum points out that the sea water of the geological period when the ancestors of mammalian forms adapted themselves to a terrestrial life was probably closely similar in its inorganic composition to blood serum.

media for the carrying out of the complex chemical processes of the body.²

(5) *To regulate body temperature.* The body owes its ability to regulate its temperature (p. 624) largely to the water of the blood and tissue fluids. Water possesses three qualities which fit it pre-eminently to fulfil this purpose.

(a) The *specific heat*³ of water is considerably higher than that of any other liquid or solid. On account of this great heat storage power of water, sudden changes of body temperature are avoided and even a cold-blooded animal such as the frog has, due to this purely physical quality, some ability to maintain a relatively constant body temperature against transient fluctuations in environmental temperature. A man of average weight develops 3000 Calories in 24 hours. This amount of heat is capable of raising the temperature of his tissues (which are mostly water) only about 32°C. Heat elimination (radiation, etc.) is able to keep pace with heat production and the body temperature varies but slightly within normal limits. But it has been pointed out by L. J. Henderson that if the tissues had the low heat storage capacity (spec. heat) of most substances, an amount of heat equal to 3000 Calories would raise the temperature of the tissues and fluids of the body by from 100°–150°C.

(b) *High conductivity.* The thermal conductivity of water is greater than that of any other ordinary liquid. The advantage of this in the dissipation of heat from deeply situated regions of the body is obvious.

(c) *High latent heat of evaporation.* More heat is required for the vaporization of water than for that of an equivalent amount of any other liquid. 1 cc. of water requires about 0.6 Calories (large) for its vaporization. This figure is 50 per cent higher than that of water's closest competitor. Fluid is being constantly lost from the body through evaporation from the lungs and skin. A large amount of heat is lost in the process (p. 623).

These physical properties of water which make it ideal as a heat regulating medium are enhanced by other purely *physiological factors*. The mobility of the blood, and the readiness with which it may be quickly redistributed in the body, combined with the unique physical properties of the fluid itself, render it so highly efficient as a regulator of body temperature. The blood may in a moment be brought from deeper to superficial regions and spread out in fine vessels over a broad area just beneath the skin, and in this way will greatly increase the radiation of heat. At another instant, in order that heat may be conserved, the fluid is drained from the surface areas and collected in

the deeper parts of the body—internal organs, muscles, etc.

(6) *Protective and regulatory.* The blood and lymph contain certain chemical substances of a complex nature, antitoxins, lysins, and other antibodies, which are the basis of the body's defence against injurious agents of various kinds. The circulating fluids are also the vehicle by which the hormones of the different ductless glands are brought into direct contact with the cells of the tissues.

THE COMPOSITION OF BLOOD

The blood is a highly complex fluid in which solid elements are suspended—the *corpuscles or blood cells*. Its specific gravity is from 1.050 to 1.060 and its viscosity from 5 to 6 times that of water. If blood is centrifuged before it has had time to clot, or if clotting is prevented by special means (p. 91), the solid elements are thrown down and separated from the fluid portion. The latter is called the *plasma* and contains *proteins*, as well as many organic and inorganic substances in solution—nutritive and excretory materials, antibodies and hormones, and other substances of an unknown or imperfectly known chemical constitution. The specific gravity of plasma is normally around 1.027 but varies with the protein concentration. The cells constitute about 45 per cent of the volume of human blood, the plasma 55 per cent. In the following table scheme are given the constituents of the blood, grouped upon a physiological basis.

Whole blood:

A. Cells:

- (1) Red corpuscles or erythrocytes
- (2) White corpuscles or leucocytes
- (3) Platelets or thrombocytes

B. Plasma:

- (1) *Water*, 91 to 92 per cent
- (2) *Solids*, 8 to 9 per cent
 - (a) *Proteins*, 7 per cent, Serum albumin, serum globulin and fibrinogen.⁴
 - (b) *Inorganic constituents*, 0.9 per cent. Sodium, calcium, potassium, magnesium, phosphorus, etc.
 - (c) *Organic constituents* (other than protein). Non-protein nitrogenous substances, (urea, uric acid, xanthine, hypoxanthine, creatine and creatinine, ammonia and amino acids) neutral fats, phospholipids, cholesterol, glucose.
 - (d) *Internal secretions, antibodies and various enzymes, amylases, proteases, lipases, esterases, etc.*

² The dielectric constant of water upon which the ionization of substances in aqueous solution depends is higher than that of any other liquid.

³ The specific heat of a substance is defined as the number of calories required to raise 1 gram of the substance one degree Centigrade.

⁴ Plasma from which the fibrinogen has been removed through clotting (p. 88) is spoken of as serum.

INORGANIC CONSTITUENTS

The concentration of the plasma in the various inorganic materials is given in table 1.

It will be noted that the plasma is relatively rich in sodium and calcium but poor in potassium and magnesium whereas in the cells conditions are reversed, these showing a relatively high concentration in potassium and magnesium but being lacking in sodium and calcium. The iron is confined almost exclusively to the red cells and most of it is in the hemoglobin molecule. A very small proportion of the iron of the cells, however, is in some other form. It has been suggested that this is bound loosely with the lecithin of the cell stroma (p. 7).

40 mgm. per 100 cc. and the greater proportion of this is in the cells.

The inorganic and ester fractions are extracted from blood by the precipitation of the proteins with trichloroacetic acid and filtering. The phosphorus contained in the filtrate is spoken of as the acid soluble phosphorus. Upon extraction of blood with alcohol-ether the lipid phosphorus is obtained. The phosphorus of blood is therefore separable into two classes.

- (1) *The acid soluble which includes*
(a) Inorganic phosphorus
(b) Ester phosphorus
(2) *Alcohol-ether soluble, i.e.,*
lipid phosphorus.

}

organic phosphorus

The ester, or organic acid-soluble phosphorus is obtained by determining the total acid soluble P and subtracting from it the inorganic phosphorus. Of the

TABLE 1
Inorganic constituents of plasma, red cells and whole blood, milligrams per 100 cc. average values

	SODIUM	POTASSIUM	CALCIUM	MAGNESIUM	CHLORINE	IODINE	IRON	COPPER	TOTAL BASE CC. N/10 NaOH
Plasma.....	340	20	10	2.7	370		0.1		160
Cells.....	0	420	0	6.0	190		100.0		
Whole blood.....	160	200	5	4.0	250	0.01	45.0	0.1	

The concentrations of these various inorganic constituents are also commonly expressed as milli-equivalents (m.equ.) per liter. Thus serum contains 100 mgm. of calcium per liter. The molecular weight of Ca is 40.07. So being divalent its milli-equivalent is 20.03. The concentration of calcium in serum is therefore $\frac{100}{20.03} = 4.9$ milli-equivalents per liter. Sodium is monovalent and has a molecular weight of 23; serum therefore contains $\frac{3400}{23} = 147.8$ m.equ. per liter.

Phosphorus

Four phosphorus compounds exist in blood. One of these is *inorganic phosphorus* (orthophosphate). The three other phosphorus fractions are in *organic* combination and are as follows.

- a. *Ester phosphorus*, e.g., diphosphoglycerate, adenosinetriphosphate, hexose phosphates, glycerophosphate.
- b. *Lipid phosphorus*, e.g., the phosphatides lecithin, cephalin, sphingomyelin.
- c. *Nucleic acid phosphorus*.

According to Kay the nucleic acid phosphorus in normal human blood is negligible. It is derived from the nuclei of white cells and the reticulum of the reticulocytes. In abnormal blood containing a large number of leucocytes, reticulocytes or nucleated red cells this fraction may however constitute a considerable proportion of the total phosphorus.

The inorganic phosphorus (3 mgm. per 100 cc.) is according to most observers about equally distributed between cells and plasma. The quantity of organic phosphorus in blood is many times greater than the inorganic. In whole blood it amounts to from 35 to

ester phosphorus, all of which is intracellular, about one-quarter is hydrolyzable by bone phosphatase (p. 716). The hydrolyzable portion is mainly adenosinetriphosphate, and the non-hydrolyzable part mainly diphosphoglycerate. Since the nucleic acid phosphorus is negligible in normal blood, the acid soluble + the alcohol-ether soluble phosphorus equals the total phosphorus as determined by wet-ashing.

In the following table is given the distribution of inorganic, ester and lipid phosphorus in normal blood.

Phosphorus in whole blood
Milligrams per 100 cc., average figures

1. Total Phosphorus..... 40
2. Total acid soluble—90 per cent in cells..... 27
3. Inorganic—in cells and plasma..... 3*
4. Ester (2—3)—practically all in cells..... 24
5. Lipid (1—2)—in cells and plasma..... 13

* In infants and young children, the inorganic phosphorus is from 1 to 3 mgm. per cent higher than it is in adults.

The phosphorus compounds of the blood and tissues play an important rôle in maintaining the electrolyte equilibrium within the red cells and in regulating the

acid base balance. Diabetic acidosis, for example, and the acidosis induced by the ingestion of ammonium chloride, are accompanied by increased excretion of phosphorus in the urine and a pronounced reduction of the organic acid-soluble phosphorus in the blood cells. Reverse changes occur in alkalosis; the reduction in the chloride of the blood following pyloric obstruction, and the alkalosis caused by over-breathing are associated with a reduction in the urinary excretion of phosphates and an increase in the inorganic and ester phosphorus of the blood. In renal insufficiency, the inorganic phosphorus in the plasma and cells and the ester phosphorus (diphosphoglycerate) in the cells are greatly increased. The inorganic and ester phosphorus are reduced in rickets but a rapid increase accompanies the healing process. The inorganic phosphorus is diminished after the injection of insulin and in hyperparathyroidism (p. 708). In anemias associated with high reticulocyte counts and in leukemia, the concentration of ester phosphorus in the blood is increased. The inorganic phosphorus is increased in some forms of tetany.

ORGANIC CONSTITUENTS

Plasma proteins

The concentration of total protein in the plasma and the proportions of the three fractions vary from species to species but under ordinary conditions of health remain relatively constant between individuals of the same species.

The values for human plasma of total protein and of the different fractions are given in the table below.

Protein in human plasma

Grams per 100 cc., average values

Total Protein.....	7.1
Fibrinogen.....	0.27
Serum globulin.....	2.7
Serum albumin.....	4.1
Ratio of three fractions (approximately).....	1-10-15
Alb./Globulin ratio.....	1.51

Serum globulin can be separated into two fractions—*euglobulin* and *pseudoglobulin*—by 1.0 molar sodium sulphate, which precipitates the former. Fibrinogen has been isolated and prepared in crystalline form. X-ray diffraction studies indicate that its molecule is structurally similar to such fibrous proteins as collagen and myosin (see p. 538). The molecular weights of the plasma proteins are given in Chapter XLVII.

In some animals the globulin is equal to or exceeds the albumin. Of the three fractions fibrinogen is always in lowest concentration and it is considerably

lower in human plasma than in that of some animals (e.g., 0.58, 0.72, 0.60 gram per 100 cc. in dog, cow and goat respectively).

as physiological

PATHOLOGICAL VARIATIONS IN CONCENTRATION. A rise in the fibrinogen and globulin fractions occurs in pulmonary tuberculosis, pneumonia, septic infections and pregnancy. A relative increase in total plasma protein results from a reduction in the water of the plasma (an hydremia, p. 19). The fibrinogen is increased in tissue injury of various sorts and in parathyroid overdosage. It is markedly reduced in animals by liver damage, occlusion of the hepatic vessels, after hepatectomy and in various clinical conditions involving the liver, e.g. phosphorus poisoning, acute yellow atrophy, etc. The concentration of *total* protein is reduced after hemorrhage (since the blood volume is for a time made good by the passage of a saline fluid from the tissues into the vessels), in nephritis, as a result of malnutrition, during pregnancy and lactation and in parenchymatous liver disease. After hemorrhage, the regeneration of fibrinogen occurs more rapidly than that of the other proteins. Globulin is regenerated more rapidly than is albumin. The regeneration of all three fractions, but especially of the albumin, is favored by a high protein diet. In nephritis and in malnutrition the low concentration of total protein is due chiefly to a reduction in the albumin fraction (p. 405). The globulin depletion is less pronounced so that the albumin-globulin ratio is lowered. The fibrinogen concentration is little affected.

ORIGIN. In the *embryo*, the mesenchyme cells through a process of secretion or by the actual solution of their substance furnish the fluid (embryonic plasma) which floats the primitive blood cells (p. 77). The albumin fraction is formed earlier than the other proteins which do not appear in the plasma of the chick embryo until after the 14th day of incubation.

In the *adult*, five possible sources of the plasma proteins have been suggested—namely, disintegrating blood cells (red or white), the general tissue cells, reticuloendothelial cells of spleen, bone marrow, etc., and the liver. We do not know with certainty the origin of the albumin and globulin fractions, though it is more than probable that they are produced in the liver, for they undergo a pronounced reduction in conditions which interfere with hepatic function. The evidence points definitely to the liver as the site of fibrinogen production since as mentioned above

the concentration of this fraction is reduced by liver damage or hepatectomy. When the liver returns to a healthy state after injury has been induced by an agent such as phosphorus or chloroform, the fibrinogen level also returns to normal. Following slight liver injury or during the repair of a hepatic lesion, which might be expected to stimulate the functional activity of the organ, the fibrinogen may be actually higher than normal.

FUNCTIONS. (1) Fibrinogen is essential for the clotting of the blood (p. 88).

(2) All three proteins serve to maintain the osmotic pressure (p. 23) of the blood. The large

that of albumin. In equivalent concentrations, serum albumin has an osmotic activity 2.4 times that of serum globulin (Keys).

(3) *Viscosity.* The proteins give a certain viscosity to the blood which is a factor in the maintenance of the normal blood pressure (p. 122).

(4) They aid in the regulation of the acid-base balance of the blood (p. 106).

(5) *Stability of the blood* (see p. 50). The globulin and fibrinogen fractions influence the tendency of the corpuscles to adhere to one another and form rouleaux or clumps.

(6) *Trephones.* Carrel has shown that the leucocytes prepare substances from the plasma

molecules of the proteins do not pass readily through the normal capillary membrane. The osmotic pressure which they exert amounts to, in man, between 25 and 30 mm. Hg. The pressure which each fraction exerts is inversely related to the size of its molecule and directly related to its concentration in the plasma. The molecular weight of fibrinogen is over 200,000 and its concentration is low; it therefore contributes little toward the total osmotic pressure. Albumin is in the highest concentration and its molecule has the least weight (70,000-75,000). The osmotic pressure of the plasma, therefore, depends largely upon this fraction. The molecular weight of serum globulin is between 150,000 and 190,000 and its concentration is considerably less than

proteins which are essential for the nourishment of tissue cells grown in cultures. These substances he has termed trephones (p. 74).

(7) *Immune substances* are associated with the globulin fraction which is increased during the process of immunization. They appear to be attached to the globulin molecule.

(8) They serve as a reserve of protein upon which the body draws during fasting or when the protein intake is inadequate.

Plasmapheresis. The importance of the plasma proteins is demonstrated by this procedure which consists in bleeding an animal and returning the red cells suspended in Locke's solution to the body. "Shock" results, followed by death when the total protein is reduced to between 1 and 2 per cent. No

ill effects result however if the cells are suspended in serum before they are re-introduced. When depletion of the proteins is not carried to the point where fatal shock ensues, a marked rise in protein concentration occurs within 15 minutes which indicates that during this time a store of preformed protein is drawn upon for the replacement of the protein which has been removed. The regeneration is slower after this though fairly rapid for the first 24 hours. It becomes progressively slower during succeeding days. The proteins are restored to the normal level in from 2 to 7 days, provided that the diet contains a sufficiency of high quality protein.

The non-protein nitrogen (N.P.N.) or non-coagulable nitrogen of blood

By the term non-protein-nitrogen is meant the nitrogen of those substances e.g. urea, uric acid creatinine, etc., listed on page 5. They may be extracted from blood or plasma by treating either of these with a reagent, such as trichloroacetic acid, which precipitates the proteins, filtering and determining the nitrogen in the filtrate. These substances are in part absorbed with, or derived from the food, and in part are the waste products of tissue catabolism. The total N.P.N. of whole blood amounts to from 28 to 40 mgms. per 100 cc. It constitutes from 1 to 2 per cent of the total nitrogen of the blood. Its concentration in the cells is nearly double that in the plasma. The proportions of the different constituents are given in table 2.

The term undetermined nitrogen embraces the nitrogen of ammonia, purines, and other non-protein substances of unknown nature.

PATHOLOGICAL VARIATIONS IN N.P.N. The N.P.N. at any given level represents the balance struck between the quantity of nitrogenous waste products entering the blood and the quantity excreted in the urine. In renal insufficiency therefore, the non-protein nitrogen is elevated, and in certain cases may be ten times the normal. On the other hand, a rise in the N.P.N. occurs in conditions, such as fevers, which are associated with excessive tissue catabolism. In the later months of pregnancy the N.P.N. is reduced. The reduction has been attributed to the diversion of nitrogen to the growing fetus and the reduction of protein catabolism in the maternal tissues.

The following is a list of the chief conditions associated with an elevation of the N.P.N. of the blood.

- Adrenal insufficiency
- Dehydration
- Haemorrhage into the gastrointestinal tract
- Infectious fevers, lobar pneumonia
- Intestinal obstruction
- Parathyroid intoxication (in animals)
- Peritonitis
- Renal insufficiency

Cholesterol (see chapter LI, and p. 649)

CHAPTER II

THE RED CELLS OR ERYTHROCYTES

THE SIZE, SHAPE AND STRUCTURE OF THE RED CELL

Human erythrocytes are disc-shaped, non-nucleated elements having a mean diameter of 7.2 microns (0.0072 mm.) and a thickness of about 2.2 microns. As a result of osmotic changes¹ the diameter increases with a shift in the acid-base balance of the blood toward the acid side. The cell is therefore slightly larger in venous than in arterial blood; its diameter is increased by about 0.5 μ in muscular exercise and reduced by forced breathing. The central portion of the cell is much thinner than its edges, which appear heaped up into a circumferential mound around a central depression. This construction gives it a biconcave contour or a roughly dumb-bell outline when viewed edgewise (figs. 1 and 2).² The average area of a red cell is 120 square microns and the volume 85 cu. microns. The mature erythrocyte can scarcely be considered a living cell in the ordinary sense, since it possesses no nucleus and does not consume an appreciable amount of oxygen. Young (nucleated or reticulated) cells, on the other hand, and the nucleated cells of

¹ These are the average dimensions of the cell measured in dry films. In the fresh state the diameter is larger by about 0.8 microns. There is considerable variation between the diameter of the smallest and largest cells found in a sample of normal blood. The range for dried films is shown in figure 2.

² Hartridge has pointed out the advantage of this design for the transport of oxygen. Of all geometrical figures the sphere is the one in which its centre is equidistant from all points upon its surface. The adoption of this form by the red cell would therefore have ensured the diffusion of oxygen to all parts of its interior at equal rates. But a sphere has the disadvantage of possessing the smallest surface in relation to its mass. A thin disc, on the other hand, presents an almost maximal surface area in relation to its bulk, yet in such a shape all parts on the surface are not equally distant from its center; the ends are further removed than the sides. The shape of the red cell—a thin disc with elevated rounded edges—is a compromise between these two forms. It secures the advantages of equal and rapid diffusion of oxygen to its interior and a relatively large surface area for the absorption of the gas.

The biconcave form also gives the red cell a mechanical advantage, in that the changes in volume which the cell undergoes from time to time are enabled to be effected with a minimal amount of tension being placed upon the cell membrane. The membrane covering the concavity of the cell moves freely out or in "like the bottom of an oil-can" as the cell increases or diminishes in volume.

lower vertebrates consume a considerable quantity of oxygen.

The red cell is bounded by a membrane made of protein in association with the lipid materials, lecithin and cholesterol. Though this membrane has not been demonstrated histologically, indirect evidence indicates its presence and suggests that it consists of an outer and inner layer of protein, each probably only a few molecules thick and enclosing between them three or four layers of lipid. It behaves as a semipermeable membrane. The body of the cell possesses a sponge-like *stroma* made of the same or similar materials probably in the form of a gel. The protein is a paraglobulin, small quantities of nucleoprotein are also present. In the meshes of the stroma, or more likely actually bound up in the stroma substance itself, the respiratory pigment *hemoglobin* is held. The fact that mechanical division of the cell, even into the finest particles fails to liberate the hemoglobin, supports the conception of a very intimate association of the pigment with the cell stroma. The water content of the cell is lower than that of most cells of the fixed tissues, amounting to about 60 per cent. Hemoglobin makes up from 80 to 90 per cent of the total solids of the cell (and about 34 per cent of its fresh weight). Other proteins (0.5 to 1 per cent) phospholipids (lecithin and cephalin) and cholesterol (0.4 and 0.3 per cent respectively), inorganic salts (fig. 3), urea, amino acids, creatine, etc. make up the remainder of the cell solids. Potassium is the principle base in the human erythrocyte, and sodium in the red cells of the cat and dog. The specific gravity of the red cell is 1.091.

When a drop of freshly drawn normal blood is placed on a glass slide and examined under the microscope, many of the erythrocytes are seen to group themselves together with their broad surfaces in contact, like a pile of coins. This arrangement of the cells is spoken of as *rouleaux*. The blood loses the property of *rouleaux* formation a few hours after it has been shed, or if the cells, as in acholuric jaundice (p. 61) tend towards a globular form. An exaggerated tendency to the formation of *rouleaux* is seen in certain states and leads to an increase in the sedimentation rate of the blood cells (p. 50).

FIG. 1. Diagram showing dimensions of the red cell.

of the extra cells occurs within the first ten days, but for a few days the red cell count shows a progressive fall; for some weeks after this the count remains considerably above that of the adult. The total number of red cells in the body estimated upon the basis of 5 million per cubic millimeter is about thirty-five million million (35,000,000,000,000).

FIG. 2. Red-cell-diameter distribution curve for healthy men (after Price-Jones).

NUMBER

The average number of red cells in man is usually given as 5,000,000 per cubic millimeter for males, and 4,500,000 for females. The normal values are somewhat higher than the foregoing and 6,000,000 is not a very unusual figure for a robust male subject. Slight variations in the number of red cells, amounting to about 5 per cent, occur throughout the twenty-four hours. The count is lowest during sleep, becomes elevated after arising and increases gradually throughout the waking hours. At birth and in infancy the red cells are somewhat more numerous than in later life, but the earlier figures of 7 and 8 millions for the newborn child have not been confirmed by later work. Destruction of a large proportion

FIG. 3. Diagram showing composition of the red cell.

PHYSIOLOGICAL VARIATIONS IN THE NUMBER OF RED CELLS

Increase in the number of red cells occurs under the following conditions:

(a) HIGH ALTITUDES. It was first shown by Viault in 1889 that the inhabitants of mountainous regions, especially where the elevation above the sea is 10,000 feet or more, have constantly a much higher red cell count than persons living at sea level. The natives of some regions in the Peruvian Andes, where the altitude is 14,000 feet or more, have a red cell count 30 per cent above the normal (over 7 million per cubic millimeter). Not only the natives, but travellers sojourning even for a short time at these altitudes undergo an increase in the number of their red cells. The corpuscular increase is directly proportional to the altitude, as may be seen from table 3.

It is perhaps necessary to point out here that an increase or a decrease in the red cell count does not of itself inform one of an increase or decrease in the red cells of the body as a whole. The red cell count gives only an estimate of the *number of cells per unit quantity of blood* (p. 14). A reduction in the amount of plasma or of the water of the blood, for instance, would cause the *proportion* of red cells in the specimen to be increased. The increase in the red cells at high altitudes is, however, not simply due to loss of fluid and a greater concentration of the blood, for estimations of the total volume of blood in the body (see p. 16) prove that there is an *absolute* increase in the number of circulating cells. How is the increase brought about? Since a rise in the red cell count occurs so very soon after a person has been exposed to the rarefied atmosphere, the possibility is at once suggested that the red cells, under ordinary circumstances, are packed away from the general circulation—in a storehouse of some kind—but are quickly mobilized upon demand. When the functions of the spleen are considered (p. 53) it will be seen that this organ serves as a reservoir for red cells and is responsible for the sudden increase in their number which occurs early in the process of acclimatization to high altitudes.

The *permanent* and great elevation of the red cell count, which is a characteristic feature of the blood of natives and other persons after acclimatization to the rarefied atmosphere, cannot be explained in the same manner, for the number of cells which the spleen can put into circulation is limited. Under these circumstances there is, actually, an increased manufacture of erythrocytes by the blood-forming organ—the bone marrow. The cells which are formed by the over-stimulated marrow are discharged into the general circulation at a somewhat immature stage of their development. They are spoken of

as *reticulated cells* or *reticulocytes* since their protoplasm shows a delicate filigree or reticulum which stains with basic dyes (fig. 4 and p. 12). The ultimate cause of the corpuscular increase (polycythemia) is undoubtedly the lowered oxygen

TABLE 3

ALTITUDE IN THOUSANDS OF FEET	CORPUSCLES MILLIONS PER CUBIC MILLIMETER
0.7	4.5

From Barcroft after Hingston. In this table the altitude (in thousands of feet) multiplied by 0.225 gives a figure which approximates the increase in red cell count (in millions per cubic millimeter) above that at sea level. In this instance the count at sea level was 4.25 millions.

FIG. 4. Showing reticulocyte response to altitude (after Barcroft).

tension of the atmosphere, and consequently of the blood, since animals placed in an hermetically sealed cabinet and subjected to lowered oxygen tensions exhibit similar blood changes.

(b) MUSCULAR EXERCISE and certain EMOTIONAL STATES cause a temporary increase in the number of red cells as a result of an outpouring of concentrated blood from the spleen. This

may be looked upon as an emergency measure and, like that which occurs at high altitudes, is the response of the body to the tissues' call for oxygen.

(c) HEIGHTENED ENVIRONMENTAL temperature also causes a liberation of red cells from the splenic reservoir.

(d) Other conditions which tend to lower the oxygen tension of the arterial blood cause a rise in the number of circulating red cells. As in the response at high altitudes two factors are concerned, e.g., a discharge of blood from the spleen and a greater production of cells by the bone marrow.

Reduction in the number of red cells occurs at high barometric pressures, e.g., when the oxygen tension of the blood is higher than the normal. Animals, for example, living in deep mines have a lower red cell count than those at sea level.

ALTERATIONS IN THE NUMBER OF RED CELLS IN PATHOLOGICAL STATES

Increase in the number of red cells—polycythemia

Increase in the total number of red cells occurs as a compensatory measure in several pathological conditions and then apparently represents the response of the bone marrow to low oxygen tensions in the arterial blood. A red cell concentration of 7 million or more per cubic millimeter of blood is not unusual in the following conditions.

(a) EMPHYSEMA (p. 368) and other chronic diseases which interfere with the oxygenation of the blood in the lungs (anoxia), e.g., tracheal stenosis, pneumothorax, tumor of the lung and pulmonary tuberculosis.

(b) CONGENITAL HEART DISEASE (p. 371).

(c) AYERZA'S DISEASE, a condition associated with dilatation and marked hypertrophy of the right heart, sclerosis of the pulmonary arteries and their branches with consequent obstruction of the blood-flow through the lungs. There is extreme cyanosis; emphysema, dyspnea and attacks of asthma are common accompaniments.

(d) CHRONIC CARBON MONOXIDE POISONING.

(e) CHEMICALS, e.g., chronic poisoning with arsenic, phosphorus and manganese, gum shellac, and certain aniline dyes.

(f) REPEATED SMALL HEMORRHAGES, the polycythemia then represents an overresponse of the bone marrow to the successive blood losses.

POLYCYTHEMIA VERA (synonyms, erythremia, splenomegalic polycythemia, Vasquez-Osler disease). Unlike the preceding types the polycythemia is not secondary to any known pathological condition. The disease appears to be

primarily centered in the red bone marrow which is greatly increased in amount and hyperplastic, extending into the shafts of the bones to displace the fatty marrow, and packed with normoblasts and mature erythrocytes. Megaloblasts are absent or very scarce. The number of red cells in the circulating blood may be as high as 14 million per cubic millimeter and a count as high as 20 million has been reported. The total blood volume is greatly increased. The viscosity of the blood is of course greatly elevated (p. 122). The concentration of hemoglobin in the individual cells and the chemical and physiological properties of the pigment are normal. The size, shape and general features of the red cells as a rule show nothing unusual and the number of reticulocytes is not greatly increased.

The chief features shown by the disease apart from those of the blood itself are cyanosis (p. 372), dyspnea on exertion, enlargement of the spleen, hemorrhages and a familial tendency. Death may occur from thrombosis of the portal vein or a cerebral vessel. The circulation rate (p. 224) is slowed and the diffusion rates of oxygen and CO_2 (p. 316) through the pulmonary epithelium are reduced, though during rest the oxygen saturation of the arterial blood is usually normal. The oxygen saturation of the blood is reduced, however, during exercise. Owing to the great increase in hemoglobin concentration the actual quantity of oxygen in the blood is greater than normal. If the polycythemia were a compensatory reaction brought about by the lowered rate of diffusion of oxygen through the pulmonary epithelium, one would expect that breathing air with a high pressure of oxygen would be of benefit, but this is not the case. Exposure, in a chamber, to a high oxygen tension for several days does not effect a reduction in the number of red cells. The reduced circulation rate may result in some way from the fact that the blood contains such a large load of oxygen that the tissues can obtain their quota from a smaller quantity of blood than normally. On the other hand, the reduced circulation rate may be due primarily to vasoconstriction in some part of the circulation. Some believe that narrowing of the caliber of the vessels of the bone marrow and the resulting low oxygen tension produced thereby provide the stimulus for the overproduction of blood cells. Studies of blood lactic acid concentration in polycythemia vera following muscular exercise lend support to the idea that a sluggish blood flow through the tissues is a causative factor. In normal persons and in the secondary types of polycythemia mentioned above, a rise in blood lactate occurs, whereas in polycythemia vera exercise causes a fall. This anomaly could be explained upon the basis of a high resting blood lactate as a result of a slow blood flow and the accumulation of lactic acid in the ischemic tissues.

Exercise would then, by causing vasodilatation, especially in the contracting muscles, tend to reduce the concentration of the metabolite in the blood. That this is the probable explanation is indicated by the observation that vasodilatation induced by heat also causes a fall in blood lactate in this disease. The phenomenon appears to be of fundamental significance, and not simply the result of the high erythrocyte concentration, because it is not abolished when the red cell count is brought down to normal by treatment with *phenylhydrazine hydrochloride*, a drug commonly employed in controlling the disease. Polycythemia can be produced in dogs by the daily administration of cobaltous chloride (8 mgm. daily for 2 or 3 weeks). The high red cell count thus induced is reduced to normal by feeding with whole beef or hog liver or by the daily injection of ascorbic acid. The effect of liver suggests the presence of an hepatic hormone possessing a depressant action upon bone marrow activity.

Reduction in the number of red cells below the normal is known as anemia. The causes and varieties of anemia are manifold and will be considered in chapter IX.

An *apparent decrease or increase* in the number of red cells occurs under certain conditions which upset the water balance of the body. It has already been pointed out that the red cell count gives merely an estimate of the proportion of cells to plasma. There may, for instance, be undue retention of water in the body, and the plasma or its watery constituents may then be increased (hydremia or hemodilution). The blood is diluted, and the number of red cells per unit of blood is reduced, yet there is no absolute decrease in the number of circulating cells. Conversely, a loss of plasma or of merely the water of the blood (anhydremia or hemoconcentration) will increase the red cell count, i.e., the blood becomes more concentrated though the total number of red cells in the body is not altered. Therefore in conditions associated with extreme dehydration (p. 17) of the body the number of red cells per unit of blood is increased.

A practical point to be remembered with regard to the estimation of the red cells is that their number may be relatively increased or decreased by purely *local* alterations in blood concentration. Pronounced dilatation of the capillaries of the region of skin from which the sample has been taken will cause a local slowing of the blood stream and congestion of the part. The loss of fluid from the vessel into the tissues and the clumping of corpuscles which may result from the greater capillary pressure will give a false estimate of the number of red cells. On the other hand, pressure

made upon the part by the examiner in order to hasten the flow of blood from a skin-puncture may express fluid from the tissues which will dilute the red cells in the specimen.

FIG. 5. Hemocytometer. A. Counting-slide shown on the flat and in cross section; it consists of two platforms surrounded on three sides by a trench; scale is engraved in the center of each platform. B, scale enlarged; C, pipette for diluting the blood 1 in 200, in counting of red cells; D, pipette for diluting the blood 1 in 20, in counting of white cells.

A drop of blood after dilution with a solution of 0.9 per cent sodium chloride is placed upon each of the glass platforms and a specially made cover glass gently applied. The space, filled with the diluted blood, between the surface of the platforms and the cover glass is $\frac{1}{10}$ mm. The scale is marked off in squares $\frac{1}{16}$ sq. mm. in area. Larger squares, each containing sixteen of the smaller squares, are marked off by heavier lines. The red cells in four large squares (on each platform) are counted under the low power of the microscope. The total number of cells is divided by one hundred and twenty-eight ($16 \times 4 \times 2$) which gives the average number in one small square. Now, the depth of the fluid is $\frac{1}{10}$ mm., so the volume upon each small square is $\frac{1}{16} \times \frac{1}{10} = \frac{1}{160}$ cu. mm. If the average number of red cells in each square is 6, then since the dilution was 1 in 200, the number per cu. mm. of blood is $6 \times 4000 \times 200 = 4,800,000$. The method of counting the white cells is similar in principle; but the blood is diluted 1 in 20 with a fluid which destroys the red cells and stains the white cells.

Estimation of red cells. An estimate of the concentration of red (or white) cells may be obtained by counting them directly after suitable dilution beneath the microscope, as in the method of Thoma-Zeiss.

The instrument used for this purpose is called a *hematocrit*. The reader is referred to texts on laboratory methods for details (see also fig. 5). Another method is by means of the *hematocrit* (fig. 6). In this the plasma and corpuscles are separated from one another by centrifugal force. The blood, rendered non-coagulable, is drawn into a graduated capillary tube, placed in a centrifuge and revolved at a speed of 3000 revolutions per second for 30 minutes. At the end of this time the original blood will be found to have separated into a clear colorless column of plasma and a red column—the corpuscles. The lengths of the two columns are read off by means of the graduations on the tube. The normal proportions of plasma and corpuscles in human blood are 55 and 45 respectively. That is, the volume of cells (packed cell volume) is 45 per cent of the total volume of the specimen of blood.

FIG. 6. Hematocrit (Daland). The graduated glass tubes are filled with blood and placed in the carrier which is then rotated on a centrifuge (see text).

VARIATIONS IN SIZE, SHAPE AND STRUCTURE OF THE RED CELLS

Under physiological conditions little change in shape of the red cell occurs, though a few fragmented cells may be found in normal blood. These are, as will be seen later (p. 56), simply remnants of senile cells which have undergone a natural disintegration in the blood stream. A slight change in volume, about 7.5 per cent occurs, due to osmotic changes incident to the respiratory cycle (p. 340). The red cells at birth and in early infancy are larger than in adult life. This as well as the higher cell count is responsible for the high packed cell volume (54 per cent) of the infant's blood.

In disease the red cell is subject to many changes in size, shape and structure. The examination of the blood and the identification of the various forms of abnormal cells is an important means employed in diagnosis of the different anemias (p. 68). Only the more outstanding abnormalities can be touched upon here. The least pronounced departure from the normal blood picture is an increase in the number of reticulocytes (see frontispiece). These young red cells resemble the ordinary cells in every way except that after

supravital staining (alcoholic solution of brilliant cresyl blue added to blood in the fresh state) fine reticulum of basophilic material can be seen in the cytoplasm. The reticular material is of cytoplasmic origin and does not represent a nuclear remains. A reticulum of similar nature may sometimes be seen in cells in which the nucleus is still intact. In normal human blood the reticulocytes are from 0 to 2 (av. 0.8) per cent of the total red cell count. They are increased after hemorrhage, at high altitudes (p. 9), exercise, in acholuric jaundice (p. 61) and pernicious anemia, especially following specific treatment (p. 64) of the latter condition and during the blood crises. A rise in the reticulocyte count indicates an increased activity of the blood forming tissue—the bone marrow—when

as a result of a specific stimulus turns out a large number of young cells. The maturation of red cells, that is, the change from reticulocytes to erythrocytes, has been estimated to take from 10 to 24 hours.

The next stage in the life of the red cell is represented by the *normoblast*, which appears in the blood in several different types of anemia. This cell, as its name implies, is normal in size and shape, possesses the usual amount of hemoglobin, but contains a nucleus. The bone marrow normally holds large numbers of these immature cells, but in health they do not reach the general circulation. In pernicious anemia and other severe types of anemia large, pale, nucleated cells are seen resembling white cells (lymphocytes, p. 70). They constitute, however, a very primitive stage in the development of the red cells; they are termed *megaloblasts*. The megaloblast contains a small amount of hemoglobin, sometimes almost none. Its protoplasm contains a diffuse or punctate arrangement of basophilic material. Hemoglobin is acidophilic, so these cells stain with acid as well as with basic dyes. This phenomenon of dual staining which may also be shown by some of the

abnormal cells, is known as *polychromasia*. Other cells of various sizes and shapes may be seen in the anemias. Shrinkage of the contents of the red cell with wrinkling of its limiting membrane, as may result from immersing the cells in a hypertonic solution, is termed *crenation*. In pernicious anemia, in particular, the presence of cells of unequal sizes (*anisocytosis*) and of deformed outline (*poikilocytosis*) is common. The poikilocytes may assume the most bizarre forms; mulberry, crescent, flask or hammer shapes may appear. *Macrocytes* and *microcytes* are terms denoting cells of usual structure and without

nuclei, but larger and smaller respectively than the normal erythrocyte. In certain conditions, e.g., lead poisoning, fine dots of basophilic material, probably a porphyrin (p. 40) appear throughout the cell, giving it a stippled appearance. This abnormality is known as *punctate basophilia* (see frontispiece). In certain types of anemia rings or twisted strands of basophilic material may be seen near the periphery of the cell. These are derived from the nucleus and are known as *Cabot's rings*. At other times small nuclear fragments—*Howell-Jolly bodies*—are present in the cytoplasm.

CHAPTER III

THE BLOOD VOLUME. WATER BALANCE

It has already been pointed out that a red cell count is merely an index of the relative proportions of cells to plasma and does not permit one to say whether the body's total supply of erythrocytes is increased or diminished. The same is true, obviously, for a hematocrit determination. These two methods indicate the concentration of the blood in erythrocytes. As a general rule, however, since the volume of the blood tends, through changes in its fluid content, to regain its normal level after this has been reduced or increased, the concentration of red cells does parallel the body's total supply. Yet it will be clear from the following examples that the principle upon which these methods are based does not imply any such relationship. If an erythrocyte count be made immediately after a sudden hemorrhage, it will be found to be practically normal, since by this time little or no fluid has passed from the tissues into the blood vessels to replace the lost blood, that is, to dilute what remains in the vessels. On the other hand, if a quantity of fluid be injected into the veins of an animal the blood count will be reduced, yet no reduction in the total number of cells has occurred. Had there been no previous knowledge of the conditions present in either of these instances, the red cell count would have given quite erroneous information regarding the body's total supply of erythrocytes. This may all seem very obvious to the reader, yet before clinical methods had been devised for the measurement of the blood volume, many wrong conclusions had been drawn concerning certain types of anemia. Blood volume estimations are of value in many clinical conditions associated with a loss or gain of fluid by the body, or for the purpose of checking the results of corpuscular and hemoglobin estimations. It is also sometimes of interest to know, in experimental investigations and in metabolic studies in man, the total amounts of certain blood constituents e.g., protein, calcium, sodium, etc., as well as their concentrations.

METHODS FOR THE ESTIMATION OF BLOOD VOLUME

DIRECT METHOD

The first attempts to measure the total quantity of blood in the body were made upon animals by Weicker (1954). His method consisted in taking a small

measured quantity of the animal's blood and diluting it to 1 in 100 with normal saline.

The animal was then bled, and after the blood had ceased to flow, its vessels were washed out and the muscles minced and extracted with water. Water was then added to the collected fluid—blood and washings—until its color matched precisely the tint of the original diluted blood specimen. The total collected fluid divided by 100 gave the blood volume.

This method was also employed upon decapitated criminals (Bischoff) in order to obtain a value for blood volume of man. By this method the total blood of the body was found to be about $\frac{1}{4}$ of the body weight—that is, from 5 to 6 liters (9–11 pints) in a man of average weight.

Obviously Weicker's method is applicable only to physiological problems of the laboratory. Furthermore, it is not free from serious errors. (1) The coloring matter of the muscles interferes with the colorations. (2) The turbidity of the final solutions prevents exact color matching, and (3) the loss of blood pigment as a result of intravascular as well as extravascular clotting is considerable and leads to further error.

INDIRECT METHODS

Carbon monoxide method

For the determination of the blood volume during life one or other of two methods may be employed. The first of these is the carbon monoxide method originally devised by Grehant and Quinquaud for animals, and modified by Haldane and Smith for man. The principle of this method is based upon the following facts (a) carbon monoxide when it combines with the blood pigment (hemoglobin) gives a bright cherry red color to the blood, so that the amount of the compound formed may be estimated colorimetrically, (b) carbon monoxide displaces oxygen from hemoglobin volume for volume.

The method is carried out as follows—the oxygen capacity of the subject's blood, that is, the maximum amount of oxygen which 100 cc. of his blood will absorb—is first determined. The oxygen capacity of normal blood is around 20 cc. Since the volumes of CO and O₂ that a given quantity of hemoglobin will take up are equal this determination gives the CO capacity as well. The subject is then instructed to breathe a known amount of CO (say 110 cc.) from a bag. Subsequent color comparisons of the blood with standard color solution show that the absorption of this quantity of gas has saturated the blood say to 12 per cent of its capacity. It is a simple matter of calculation to determine from this datum how much

as would be required to saturate the blood to its full capacity, and so arrive at the total blood volume. Thus—

After the inhalation of 110 cc. of gas the blood is found to be 12 per cent saturated; therefore $10 \times \frac{100}{12} = 916$ cc. of gas would be required to saturate it to full capacity. Inasmuch as each 20 cc. of gas would represent 100 cc. of blood if this were fully saturated $\frac{916}{20} \times 100 = 4580$ cc. total blood volume.

The carbon monoxide in the blood may be estimated more accurately by gas analysis after the method of Van Slyke rather than colorimetrically. The technical difficulties of the carbon monoxide method of determining blood volume are great, and the error would appear to be considerable.

THE DYE METHOD

This method was originally devised by Keith, Rowntree and Geraghty and has largely superseded the carbon monoxide method. The degree of dilution in the plasma of a known amount of dye injected into the circulation is employed as the basis of calculation. The color of the stained plasma is compared in a colorimeter with that of a standard dye solution of known concentration. There are several qualifications required of a dye before it can be considered suitable for blood volume measurements. In the first place, of course, it must be innocuous. It must not diffuse too rapidly from the blood stream; it must color only the plasma, and not be adsorbed by the cells of the blood nor by the walls of the blood vessels. Finally, it must not change color itself after entering the blood, nor cause the liberation of pigment from the red cells (hemolysis). If it lacked these qualifications, the colorimetric readings obviously would be in dependable.

The dye most commonly employed until recent years was brilliant vital red. The method has been improved by Gregersen and his associates by the use of the blue dye T-1824 (Evans blue). Evans blue has the advantage that the error due to any discoloration of the plasma by hemoglobin (hemolysis) is minimized. This dye is also eliminated very slowly (4.8 per cent per hour) from the circulation. The color determinations are made most satisfactorily with a photoelectric colorimeter or a spectrophotometer. In the method as modified by Crooke and Morris, the proteins of the plasma samples are precipitated and removed by filtration and the colorimetric

measurements made upon the filtrate. The following is the technic employed by these authors.

Six ml. of blood are drawn from a median antecubital vein for making up a standard solution. Five ml. of a 0.70 sterilized Evans blue solution are injected through the same needle. At intervals of 20, 40 and 60 min., 3 ml. samples are drawn from the opposite antecubital vein. All samples are transferred to 15 ml. centrifuge tubes, which have been coated with paraffin wax, and which contain 30 mg. of a 2:3 mixture of potassium and ammonium oxalates. After mixing, the tubes are centrifuged for 10 minutes at 2500 revolutions per minute. The plasma is immediately removed and kept in stoppered tubes for analysis. The proteins of the plasma samples are precipitated by adding slowly 7 ml. of the precipitating reagent (1 vol. concentrated HCl and 6 vol. alcoholic phosphotungstic acid) to 1 ml. of plasma. The samples are centrifuged and the supernatant fluid removed for colorimetric determinations. A standard solution is made up by adding 0.10 ml. of a 1 in 50 dilution of the injection solution to 1 ml. of undyed plasma. Of this mixture, 1 ml. serves as a standard. This quantity of the standard solution contains 1/2500 of the total amount of dye injected; such a dilution corresponds, therefore, to a "plasma volume" of 2500 ml. A color measurement is then made on each sample.

The calculations are made as follows. When P is the plasma volume, V_1 the mean value of the colorimetric readings of the three plasma samples and V_2 the value for the standard, then

$$P = \frac{V_2 \times 2500}{V_1}$$

In order to obtain the value for the total blood volume the proportion of red cells to plasma must be determined by means of the hematocrit. If the packed cell volume is 45 per cent the plasma volume is, therefore, 55 per cent and the total plasma volume, as determined above, is, say $\frac{3000}{55} \times 100 = 5454$ cc. total blood volume.

The determinations are made with the patient recumbent and under basal conditions, some 12 to 14 hours after a meal. The loss of dye into the tissues at the site of injection must be avoided since this of course will vitiate the results which, since the plasma would be less deeply stained, would be too high. Care must also be exercised to prevent evaporation of fluid from the samples after they have been drawn. Otherwise the concentration of dye in the plasma would be raised and the readings (which would indicate a lower degree of dilution) would be too low. Determinations by the dye method from time to time on the same individual under comparable conditions give consistent results. The absolute blood volume of course will never be known exactly, since it cannot be measured

directly in the living subject. But even in the dead subject there is no reason to believe that the direct method is any more accurate than the dye method in the living.¹

NORMAL VALUES FOR PLASMA AND WHOLE BLOOD VOLUMES

The whole blood is about 1/11 and the plasma 1/20 of the total body weight, i.e., 9 and 5 per cent respectively. Expressed as volumes, the whole blood is about 90 cc. per kilogram of body weight and the plasma about 50 cc. per kilogram. The blood volume of an average sized man of normal weight (70 kgm.) is therefore around 6000 cc. Rowntree has demonstrated that the blood volume is a function of the body's surface area. It amounts to about 3.3 liters per square meter (p. 533). The blood volume per square meter is higher by about 7.5 per cent in men than in women; the plasma volumes in the two sexes are, however, about the same. That is, the larger volume in males is due to a greater number of red cells. Infants have a greater blood volume in proportion to their body weight than have adults, but a lower volume in relation to body surface. (The body surface of children is of course greater in proportion to weight than that of the adult). The greater blood volume of the infant in relation to weight is due mainly to the greater numbers of red cells, though there is also a greater plasma volume.

REGULATION OF THE BLOOD VOLUME AND THE BODY'S WATER BALANCE

The blood volume and its variations cannot be considered apart from the fluid content of the body as a whole. The blood plasma constitutes but a small proportion of the total water of the body, being about 5 per cent of the body weight, whereas the extravascular fluids (extracellular 15 per cent, intracellular 50 per cent) make up 65 per cent of the weight of the body. Blood volume regulation is a question of balance between the fluid within the vessels and in the tissues. When conditions arise which tend to lower or raise the volume of blood, counter forces (p. 26) come into play which restore the normal level. When circulating fluid is lost, the vessels replenish themselves from the extravascular spaces. On the other hand, any tendency for the blood volume

to rise is met by a discharge of the excess into the tissues or along the excretory route. So, a balance is struck, and in health the blood volume is maintained remarkably constant. For example, after the intravenous injection of a large quantity of saline, the volume of circulating fluid (though raised temporarily) is brought back to normal within 30 minutes or less. On the other hand the loss of blood fluid, as by hemorrhage, immediately calls into action processes which may, in a remarkably short space of time, replenish the blood volume. When an animal is bled to death, at a not too rapid rate, the blood which is withdrawn is found after a few minutes of bleeding to have become diluted—demonstrating the promptness with which water (water and salts) has been absorbed into the vessels.

A. THE WATER INTAKE

The fluid of the body is replenished in two ways: (a) by the ingestion of liquids of moist food; (b) by the water formed in metabolism through the oxidation of the hydrogen of the food, and from the body tissues themselves. The following table from Rowntree compiled from the data of Magnus-Levy gives the quantities of water produced by the metabolism, respectively, of the three main food stuffs and of alcohol.

100 grams of fat	yield	107.1 grams water
100 grams of starch	yield	55.1 grams water
100 grams of protein	yield	41.3 grams water
100 grams of alcohol	yield	117.4 grams water

An ordinary mixed diet yields in this way 300 to 350 grams of water daily, or about 10 grams per 100 Calories. When no food or water is taken, the body materials themselves are used for this purpose, the glycogen protein and fat supplying important quantities of water. The camel's hump, for instance, which is largely composed of fat, is a reservoir for large amounts of water, and the clothes moth kept in a desiccated and fed upon perfectly dry food lays eggs which are 80 per cent water.

B. THE WATER OUTPUT

Water is lost from the body in the feces, in the urine and saliva and by the evaporation of water from the skin and lungs. The daily loss through these several channels is given in the following

¹ The blood volume as estimated by the foregoing procedures gives the volume of circulating blood and does not include the blood of the spleen (p. 53) which plays the rôle of a reservoir.

an averaged sized man at light occupation in a temperate climate.

Water (at average temperature and humidity).....	500
Inspired air (at average temperature and humidity).....	350
Expired air (at average temperature and humidity).....	1500
Sweat.....	150
Total.....	2500

The loss in the saliva is negligible under ordinary circumstances but may be considerable in mouth breathing (as a result of evaporation) and in those addicted to the spitting habit.

The water lost by the skin and lungs varies greatly with the temperature and relative humidity of the atmosphere and with the extent of the muscular exercise indulged in. At ordinary temperatures the loss of water by the skin is not perceived, since the sweat evaporates as quickly as it is formed. This insensible perspiration, as it is called, also includes the evaporation of water from the surface of the body apart from actual sweat secretion (see p. 626). The amount of the *insensible perspiration* has the average value given above but may be many times this value. When the air is hot, for example, the rate of sweat secretion and the rate of evaporation are greater than at lower temperatures. Relative humidity and air movement also influence the rate of evaporation. So, in humid, still atmospheres sweat secretion is more evident though it may be no greater than in a drier atmosphere when evaporation is more rapid. Large quantities of sweat are secreted as a result of muscular exercise or when as in the tropics the temperature is high. In hot climates the daily secretion may amount to 3000 cc. daily and in very torrid atmospheres it may be as much as 10 liters. This necessitates the drinking of an equal quantity of fluid in order to maintain the normal water content of the body, since the intake must equal the output. For the adult, the water requirement from all sources and under ordinary circumstances is around 2500 cc. daily or about 100 cc. per Calorie of food intake. This usually means that about 800 cc. exclusive of that derived from solid and semi-solid food must be drunk.

At ordinary temperatures the inspired air contains negligible quantities of water whereas the expired air is almost saturated with moisture. Any condition which increases the pulmonary

ventilation therefore increases the water lost by this route.

Protein is laid down in the body with water (about 3 grams of water per gram of solid). During growth or convalescence from wasting diseases retention of water therefore occurs, i.e., the intake of water including that derived from solid food exceeds the output. Fat and glycogen however are accompanied by a relatively small water storage. Water retention occurs following a change from a high fat to a high carbohydrate diet; on the other hand, water is lost from the body when the diet is changed from carbohydrate to fat. These facts are difficult to explain but they are not due, as was previously supposed (Zuntz), to a large volume of water being bound to glycogen. A high or low intake of sodium chloride causes an increase or decrease, respectively, in body water (see p. 407).

DEHYDRATION

When the output of water exceeds the intake, the body's water content obviously will be reduced. That is, the body is in negative water balance and the condition known as dehydration results. The following are the average normal percentages of water in several tissues:

	per cent
Muscle.....	75-80
Connective tissues.....	60
Adipose tissue.....	20
Bone (marrow-free).....	25
Blood:	
Plasma.....	92
Cells.....	60
Nervous tissue:	
Gray matter.....	85
White matter.....	70

Water composes about 70 per cent of the body's weight, the extracellular fluids accounting for about 20 per cent. The muscles contain about half, the skin a fifth and the blood only about a fourteenth of the body's water. Body water is practically all in the free state. That is, substances can be dissolved in it and it can be entirely removed by ultrafiltration. In other words, the quantity of so-called "bound" water, i.e., water bound with colloids or in other ways, is negligible. Water may be lost from the tissue cells or from the tissue spaces and blood, or from both intracellular and extracellular sites. Gamble, Ross and Tisdall therefore partition body fluid according to its location into two portions. In the

interstitial fluids and blood, the concentration of potassium is only a very small fraction of the sodium concentration. In the tissue cells, on the contrary, the concentration of Na is much less than that of K (see table 3½). The Na and K contents of the water excreted in certain pathological states is therefore employed as a means of estimating the proportions derived from extracellular and intracellular sources respectively. Thus, during the subsidence of nephritic edema, or of the subcutaneous accumulations in myxedema following thyroid treatment, the excreted water contains a large excess of sodium over potassium. During the fluid loss which results from a diet of glucose and water the loss of extracellular fluid as well as the shrinkage of the tissues causes an increased excretion of both Na and K (Byrom).

TABLE 3½
Concentrations of base in the water of blood plasma and in the water of muscle tissue
(After Gamble, Ross and Tisdall)

	PER 100 CC. PLASMA	PER 100 CC. PLASMA WATER	PER 100 CC. MUSCLE TISSUE	PER 100 CC. MUSCLE WATER
	mg.	cc. 0.1 N	mg.	cc. 0.1 N
Na ⁺	330	157.7	80	45.8
K ⁺	20	5.6	320	108.0
Ca ⁺⁺	10	5.5	8	5.3
Mg ⁺⁺	3	2.7	21	23.0
Total.....		171.5		182.1

Water of blood plasma is taken as 91 per cent by volume and water of muscle tissue as 76 per cent of weight.

In the early stages of a fast the excreted water has a high sodium content; after prolonged fasting its relatively high potassium content indicates an intracellular origin (pp. 608, 631). A loss of one-fourth of the body water is usually fatal.

Causes of Dehydration

Dehydration may result from:

(a) Simply the *deprivation of fluids*, for under such circumstances water, though its excretion in the urine and sweat is reduced, continues nevertheless to be lost from the body in considerable amounts. At high environmental temperatures or in fever, the condition will supervene more rapidly owing to the greater loss from the lungs and skin. Mental patients may readily become dehydrated as a result of their refusal to drink.

(b) *Excessive loss of water* may result from persistent vomiting (e.g., pyloric or intestinal obstruction) prolonged diarrhea, or the excretion of large quantities of urine or sweat, especially when accompanied by a restricted water intake. In the acute diarrheas of infants, dehydration and loss of weight may occur very rapidly.

(c) *Reduction in the total quantity of electrolyte* in the body fluids. The electrolytic concentration of the body fluids, both extracellular and intracellular, is maintained constant through the elimination or retention of water. That is, a reduction or increase in the total electrolytes which comprise chiefly the basic radicles Na (extracellular) and K (intracellular) and the acid radicles HCO₃ and Cl, is accompanied by a corresponding decrease or increase in the volume of body water. The sum of the basic elements and acid elements of course must balance. Loss of Cl can be made good by the retention of H₂CO₃ and a rise in plasma bicarbonate. Excreted base, however, can be replaced only by basic substances supplied in the food. The total concentration of electrolytes in the body fluids is therefore dependent upon the stores of total base. For example, in pyloric or high intestinal obstruction (p. 510) fluid is secreted in large quantities into the gastrointestinal tract. The fluid may be vomited or may collect and remain in the dilated part of the canal above the obstruction. (The latter occurrence is the rule in the rabbit which cannot vomit.) In either case the secretion of large quantities of gastric juice entails loss of blood chloride. A similar chloride loss is induced in animals by means of a gastric fistula fashioned by sectioning through the pylorus, stitching the stomach opening to the abdominal wall and allowing the gastric juice to drain to the exterior. In the foregoing instances, the chloride depletion causes at first no ill effects, the normal concentrations in electrolytes of the blood and tissue fluids being maintained for a time by the retention of CO₂, and, as a consequence of this, an increase in bicarbonate. The compensation for the Cl loss leads however to alkalosis which is then countered by an increased excretion of base in the urine. This of course is accompanied by diuresis; marked dehydration results.

On the other hand, the continued loss of pancreatic juice (p. 451) to the exterior causes immediate depletion of base; plasma bicarbonate is reduced. In the adjustment of the acid-base balance the excess of acid radicles is excreted in urine; this again entails a loss of water. Similar

the ingestion of acid-producing salts causes a depletion of base, which is used for the neutralization and excretion of the acid radicles. Such salts therefore act as diuretics and dehydrating agents.

(d) *The injection of hypertonic solutions* (p. 30) into the blood stream. When a strong sugar or salt solution is injected, the temporary rise in the osmotic pressure of the blood causes a flow of fluid from the tissues into the vascular system until equilibrium is re-established. The blood volume is increased, but is soon returned to normal by the loss of the excess fluid into the tissues and its eventual excretion via the kidney and bowels. A net loss of body water results.

Effects of dehydration

(a) *Loss of weight* due to the reduction in tissue water as well as to the actual breakdown of body substance which occurs in the effort to furnish water for the maintenance of physiological processes. Fat and carbohydrate stores are first drawn upon for this purpose and later protein. (b) *Disturbances in acid-base balance* usually toward the acid side. The diminished quantity of circulating fluid (anhydremia) and the consequent depression of oxidative processes in the tissues is held responsible for the excessive production of acid metabolites, e.g., lactic. The slowing of the renal circulation also leads to a reduced excretion of urine and the retention of acids (e.g., phosphoric) which under normal circumstances are eliminated. (c) *Rise in the non-protein nitrogen of the blood*. (d) *Rise in body temperature* as a result of the reduction in circulating fluid (see p. 624). (e) *Thirst*. Under normal circumstances this serves as a signal that the water stores of the body require to be replenished. Any fall in the water content of the tissues is reflected in the glandular activities especially of the salivary glands. Secretion is suppressed; the mouth and throat become dry and the sensation of thirst is aroused. In dehydration thirst is extreme and the mouth parched. (f) *Dryness, wrinkling and looseness of skin* and a pinched expression to the features result from the loss of subcutaneous fat and of water from the deeper layers of the skin. Other manifestations are, reduced intraocular tension and recession of the eyeball and, in infants, depression of the fontanelle.

WATER INTOXICATION

When an animal is given large quantities of water by stomach tube, especially if urinary secre-

tion is reduced by the administration of pituitrin, the tissues become "water-logged," serious symptoms ensue, e.g., depression of temperature, vomiting, convulsions and coma, which shortly end in death. Similar effects also follow in man if large quantities of water are given to a patient with nephritic edema or if in a subject of diabetes insipidus pituitrin be administered while the water intake is maintained at the usual level (see p. 739). The convulsions are probably the result of cerebral edema.

ALTERATIONS IN BLOOD VOLUME

I. REDUCTION OF THE BLOOD VOLUME

This may result from:

- (1) A loss of *whole blood* as in hemorrhage (p. 20).
- (2) *Reduction in the total number of red cells*, as a result of increased destruction or diminished production (see anemia p. 61).
- (3) Loss of *plasma* alone from the vessels as in extensive burns p. 261 or
- (4) *Loss of blood water*. This is called *anhydremia* and is simply a part of a general dehydration and so results from the same causes as the latter.²

In the reduction of blood volume resulting from hemorrhage, the concentration of the blood in cells and protein is lowered, since a watery fluid is attracted into the vessels from the surrounding tissues.

When the blood volume is lowered as a result of a loss of plasma, the red cell concentration is increased but the protein (hemoconcentration) of the plasma is little altered.

In anhydremia both the protein concentration of the plasma and the red cell count are raised. The concentration of plasma protein may increase by 50 per cent or more. The viscosity of the blood is therefore raised; the blood appears "syrupey" and flows sluggishly from an opened vein. If the anhydremia persists the red cell count and the protein concentration tend to fall again as a result of red cell and protein destruction. Then an estimation of the blood concentration may fail to give a true index of the extent of the blood volume reduction.

Exposure to cold causes a moderate loss of water from the blood to the tissues (chiefly skin muscle and probably liver), the total water content of the body remaining unaltered. It is not alto-

² Variations in blood volume from time to time due to alterations in blood water may be detected from estimations of hemoglobin or protein concentrations, or by means of the hematocrit.

gether clear by what means this movement of water is brought about. It is, however, an important factor in the regulation of body temperature (p. 624). The work of Barbour and others furnishes evidence of a nervous element in the mechanism. Animals in which the cord had been divided in the upper thoracic region when placed in a cold bath did not respond in the normal fashion. Concentration of the blood did not result and the temperature of the body fell to that of the environment (fig. 244). The control is exercised evidently through vaso-motor nerves.

Barbour and Hamilton have shown that cold applied locally after section of the splanchnic nerves causes anhydremia as a result of the transudation of water into the skin of the cooled area. They attribute the migration of water to constriction of the cutaneous arterioles and consequent slowing of the capillary blood flow, which in turn, apparently through oxygen lack, increases the permeability of the capillary wall.² It is probable therefore that exposure to cold induces blood concentration through both central and direct peripheral effects.

Posture. The blood volume of the human subject after 30 minutes or so in the erect posture is some 15 per cent less than that in recumbency. A fluid of low protein concentration leaks from the vessels of the lower limbs into the extra-capillary tissues, as a result apparently of the increased hydrostatic pressure in the capillaries of these parts (p. 25, see also p. 382).

II. INCREASE IN BLOOD VOLUME

(1) *High temperatures.* Two factors are concerned in the elevation of the blood volume which follows a rise in environmental temperature, (a) contraction of the spleen whereby whole blood is discharged into the general circulation (p. 54) and (b) dilution of the blood, water being drawn from the tissues to augment the circulating fluid. This is a reversal of the mechanism described above as occurring at low temperatures. Sweating, and increased evaporation from the body surface, if over a prolonged period, will tend to counteract these effects; the blood volume may then show a decrease, or one effect may balance the other and no change occur.

(2) *Muscular exercise.* At the beginning of

² In this experiment, however, the cold was of such a degree that it may have directly damaged the capillary epithelium.

exercise the blood volume is increased as a result of the discharge of blood from the spleen. Inasmuch as the splenic blood is relatively rich in red cells, the blood of the general circulation shows an increased cellular concentration. Later, as osmotically active substances (e.g., lactic acid) are formed in the contracting muscles, water is attracted from the vessels. The protein concentration of the plasma, and the red cell count increase. Sweating, when it ensues, tends to increase the degree of anhydremia by causing a reduction in the water content of the body as a whole. The early increase in blood volume which in animals, results from the discharge of blood from the spleen is not seen, as a rule, in man. In dogs, muscular training causes an increase in blood volume and of the erythrocyte count which persists for about a month after the termination of the training period.

(3) *Emotional excitement* in animals and in man causes an increase in blood volume due to contraction of the spleen (p. 54).

(4) *Pregnancy.* Barcroft and his associates observed in sheep a pronounced increase in blood volume in the first and last thirds of pregnancy due to an increase in plasma. The corpuscular volume showed a relative decrease.

SUMMARY OF THE PATHOLOGICAL STATES ASSOCIATED WITH ALTERATIONS IN BLOOD VOLUME

Reduction

(a) *Hemorrhage* (loss of whole blood), (b) *burn* (loss of plasma), (c) *dehydration* (loss of water), (d) *pernicious anemia* (reduction in red cells with a moderate increase in plasma), (e) *chronic anemias other than those of the pernicious type*. In these the total volume of red cells is only slightly or moderately reduced and this is to a large extent compensated for by an increase in plasma above the normal standard. The total blood volume is therefore, as a rule, not greatly below normal as calculated upon the basis of weight or of surface area. In other words, the blood is diluted and if, as sometimes occurs, the increase in plasma is greater than the reduction in red cells, a red cell count will give an exaggerated picture of the oligocythemia. (f) *Obesity*. The blood volume per kilogram of body weight is much reduced but is normal when considered in relation to the body surface. (g) *Myxedema* (reduction of both red cells and plasma but mainly of the former (fig. 7).

Increase

(a) *Polycythemia vera* (increase mainly of red cells but also of plasma), (b) *cirrhosis* of the liver (increase of plasma), (c) *leukemia* (increase in white cells and plasma), (d) *splenomegaly* with anemia—Banti's disease (increase in plasma), (e) *hyperthyroidism* (equal increases both in red cells and plasma).

It should be pointed out that the proportions of red cells and plasma may vary from the normal though the total blood volume remains unaltered. With regard to the blood volume and the proportion of cells to plasma there are therefore nine possible blood states. Rowntree has introduced

FIG. 7. Showing whole blood, red cell and plasma volumes in various diseases. Dotted lines indicate normal standards, upper for whole blood, lower for plasma (after Rowntree).

the following descriptive terminology. A normal blood volume he terms *normovolemia*. If the ratio of cells to plasma is normal as well, he calls the condition *simple normovolemia*; decrease or increase in the number of cells in relation to plasma is termed *oligocythemmic* or *polycythemmic normovolemia* respectively. *Hypovolemia* and *hypervolemia* are corresponding terms for reduced and increased blood volumes; each of these is divisible into simple, polycythemmic and oligocythemmic forms (see fig. 8).

THE EFFECTS OF HEMORRHAGE

When more than 30 per cent of the blood volume is lost rapidly the body is usually unable to repair

the loss unaided and, unless transfusion is resorted to, death results. In a healthy man the loss of 30 per cent or less of his blood, calls readjusting mechanisms into play which may bring the blood volume back to the normal level within a remarkably short time; 500 cc. or so of blood drawn for transfusion purposes are said to be replaced within an hour or so. The restoration of the blood to its previous concentration in erythrocytes, however, takes about seven weeks on the average. This time may be shortened considerably by the administration of iron and a diet containing a liberal quantity of high quality protein. Fowler and Barer found in a study of 200 blood donors that, after the removal of 550 cc. of blood, the average fall in hemoglobin was 2.3 grams per 100 cc. Regeneration of hemoglobin occurred at the rate of 0.049 gram per cent for men and 0.040 gram for women per day.

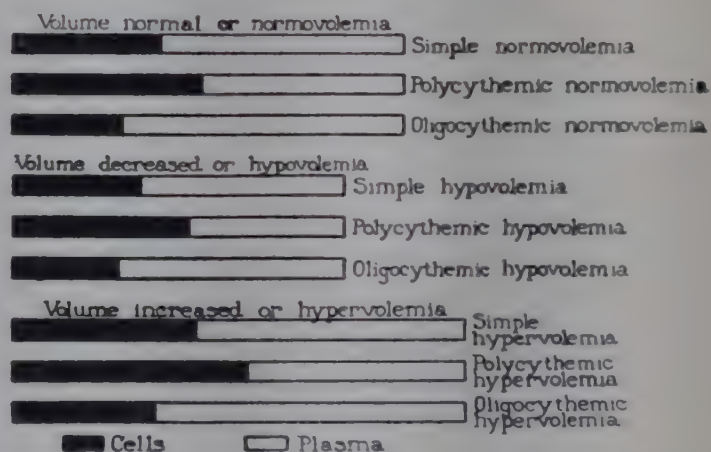

FIG. 8. The nine possible combinations of whole blood, plasma and red cell volumes (after Rowntree).

The protective mechanisms which automatically come into action after hemorrhage are several and may be divided into two groups—*immediate* or *early* and *delayed*.

A. Immediate or early effects

If the loss of blood is large, especially if it is of sudden occurrence and from an artery there is a prompt fall in blood pressure as a result simply of the reduction in circulating fluid (p. 122). If not too great, the fall in pressure is of benefit, since it helps to prevent further bleeding. A moderate loss of blood, 10 per cent of the total amount, produces little or no drop in pressure. This is especially true if the blood is lost gradually and if it comes from a vein, i.e., beyond the peripheral resistance. Under these circumstances compensatory mechanisms easily maintain the pressure of blood at its normal height.

Clotting of the blood (p. 88) which occurs within a few minutes serves to close the opening in the blood vessel. The initial drop in pressure, when such occurs, aids the formation of the clot and the effectual sealing of the vascular wound. This is also furthered in the case of an artery by the retraction of the middle fibro-muscular coat of the vessel, as well as by the curling up of its endothelial lining. These factors alone may be sufficient to stanch the flow of blood from an artery as large even as the popliteal. The blood also clots more rapidly than usual after a severe hemorrhage.

Increase in the heart rate. This is almost invariably an accompaniment of a severe hemorrhage and is one of the most valuable signs of concealed, i.e., internal, bleeding. It is brought about through carotid sinus and aortic reflexes (pp. 240 and 242) initiated by the fall in blood pressure. Reduction in blood flow through the vessels of the medulla with the consequent anoxemia of the cardiac centers may be an additional factor. Adrenaline liberation (p. 689) also probably plays a part. The increase in heart rate might under the circumstances appear to be of advantage—an attempt on the part of the heart to increase the rate of blood flow and so compensate for the reduced volume of blood by having it carry an oxygen load from lungs to tissues more frequently. It seems clear, however, from the work of several investigators (p. 216) that simple increase in the cardiac rate does not increase the output of the heart.

Contraction of the spleen and the discharge into the circulation of a large quantity of blood rich in red cells (p. 54).

Increased respiration. The anoxia of the chemoreceptors of the carotid and aortic bodies caused by the reduced blood flow (p. 346) is probably responsible for the increased rate and depth of breathing. When the blood loss is more profound, and consequently the oxygen want more urgent, long deeply drawn inspirations, and expirations of a sighing character ensue (air hunger), or periodic breathing of a Cheyne-Stokes type may develop (p. 352). Gasping respirations precede death.

Reduction in capacity of the vascular bed and redistribution of the blood. When the flow of blood has been stanching or considerably lessened by a complete or partial closure of the wound in the vessel, the blood pressure, if this had been lowered, rises again. This is the result mainly of a readjustment of the capacity of the vascular

system whereby it is made to conform more nearly to the lessened volume of blood. It is this reduction in the vascular capacity which prevents the initial fall in pressure when the loss of blood is gradual. It is effected by the reflex narrowing of innumerable small vessels (vasoconstriction) in regions such as the skin, mucous membranes, intestine and other parts not immediately essential to life. The vascular response is called into play by the underfilled state of the arteries and large veins feeding the heart (see vascular reflexes, pp. 240 and 241). This measure whereby the blood remaining in the vascular system is confined to a smaller space is of the utmost importance; it enables the essential centers in the medulla to be supplied with blood under adequate pressure to sustain their vitality. Also a greater quantity of blood than would otherwise be possible is brought to the heart to supply its muscle, fill its cavities and maintain the circulation. The withdrawal of blood from the less important parts of the body is responsible, however, for some of the characteristic manifestations of hemorrhage, notably the pallor of the skin and mucous membranes, and the coldness of the body surface. The cerebral anemia causes sensation of giddiness or faintness, flashes of light or ringing in the ears (tinnitus).

The rise in blood pressure at this stage is conducive to fresh bleeding. There is danger of the clot becoming dislodged.

B. Delayed effects

Replacement of the lost fluid. This, it has already been mentioned, commences almost upon the instant that the blood is lost (p. 16), but takes a variable length of time, depending upon the extent of the blood loss, to become complete. Fluid is drawn from the tissues into the vessels and dilutes the blood. The corpuscular concentration is therefore reduced. The protein concentration of the tissue fluid at first is relatively low so that a short time after hemorrhage the protein content of the plasma is markedly depressed. Very soon, however, the concentration of protein in the plasma shows a pronounced rise again as a result of the mobilization of protein stores. Calton found, for example, that in dogs 50 per cent of the plasma protein removed by bleeding was restored within 4 hours. The extreme thirst which the subject of acute hemorrhage suffers is the call of the tissues for fluid and indicates that their own stores are being drawn into the un-

filled vessels. The administration of water will therefore aid the body in recovering its water balance and replenishing the blood volume.

Replacement of the red and white cells finally occurs through the increased activity of the blood-forming organs. This takes several days or weeks, the rapidity of the process depending to a large extent upon the nutrition and recuperative power of the individual and upon the diet (pp. 21 and 57). While the repair process is in progress reticulated cells are found in increased numbers in the blood (p. 12).

THE FACTORS GOVERNING THE INTERCHANGE OF FLUID BETWEEN THE TISSUES AND THE VESSELS

The physical factors which determine the flow of fluid from the tissues into the blood stream as well as in the reverse direction—from the vessels to tissue spaces—are the *osmotic* and *hydrostatic pressures* of the fluids in the two situations.

Osmotic pressure

Osmotic pressure may be simply defined for our purpose here as the “attractive” or “drawing” force which sodium chloride, cane sugar and many other substances in solution exert upon the water molecules when water and a solution of one or other of these substances are separated by a membrane which allows the molecules of water to pass, but is quite or relatively impermeable to the molecules of the dissolved substance. Such a membrane is spoken of as “*semi-permeable*.” An example will make this clear.

If an aqueous solution of cane sugar be placed in a vessel and a layer of water poured gently upon its surface, the two liquids will remain separate for a time. Gradually, however, sugar molecules will diffuse upwards and intermingle with the water molecules, while many of the latter will pass downwards into the sugar solution. The diffusion process, which is quite independent of gravity or convection currents, will continue slowly until the concentrations of the two types of molecules become equal throughout all parts of the liquid. If now instead of allowing free diffusion between the two solutions to take place, they be separated by a membrane which will permit the molecules of water to pass through it, but will offer a barrier to the migration of the dissolved substance, equal and free diffusion cannot occur. Since the water is able to pass into one compartment while the sugar molecules cannot pass out, the volume in this latter compartment obviously must increase; the pressure will rise. The pressure which is developed may

amount to several atmospheres. This is the osmotic pressure, and it may be measured by the apparatus shown in fig. 9, A. As the osmotic pressure within the inner chamber increases the mercury column is raised, that is, work is performed. In order to drive water through the membrane into the outer chamber the osmotic force must be overcome. In fig. 9, B is illustrated a cylinder fitted with a piston and closed at its lower end by a semipermeable membrane. A force greater than the osmotic pressure developed within the cylinder would be required in order to filter water through the membrane. An instrument which measures osmotic pressure is known as an *osmometer*. An indirect method maybe employed, e.g., measurement of the freezing point or the vapor pressure.

It is seen therefore from the foregoing that what was spoken of as an “attractive force” is simply the usual diffusion of water molecules into a solution of sugar which, owing to the intervention of a semi-

FIG. 9. Description in text (after Parsons).

permeable membrane, cannot diffuse in the opposite direction. The actual pressure developed may be supposed to result from the bombardment of the walls of the containing vessel by the imprisoned molecules of the dissolved substance.⁴ The osmotic pressure of any solution will then necessarily depend upon the number of the bombarding molecules, i.e., upon their concentrations in the solutions. The pressure of a gas also depends upon the number of gas molecules per unit volume, and indeed it has been proved that the gas laws can be applied to the behavior of dilute solutions of cane sugar and other substances which exert osmotic pressure.

In other words, *substances in dilute solutions behave almost precisely as though they were in a gaseous state*. For instance, an amount of any gaseous substance equal to its molecular weight in grams (gram molecule)

⁴ Several theories, of which this is the simplest, have been advanced to account for the phenomenon of osmotic pressure.

at standard temperature and pressure has a volume of 22.4 liters. That is, 32 grams of oxygen at 0°C. and 760 mm. Hg occupy the same volume (22.4 liters) as 2 grams of hydrogen under the same conditions. Also, according to Avogadro's hypothesis, equal volumes of gases at the same temperature and pressure contain equal numbers of molecules, i.e., their molecular concentrations are identical. The molecular weight of cane sugar is 342 grams. Therefore, according to Avogadro's law 342 grams of cane sugar if in the gaseous state would have a volume, at standard temperature and pressure, of 22.4 liters. Conversely, 342 grams of cane sugar if confined to a volume of 22.4 liters by dissolving it in that amount of water will, if the gas laws apply, have a pressure of 760 mm. Hg at 0°C. Again, according to Boyle's law the pressure of a gas is inversely proportional to the volume at constant temperature. If therefore the same amount of cane sugar be dissolved in half the amount of water (11.2 liters) the osmotic pressure will be doubled. On the other hand, if the concentration of the molecules of sugar be reduced by dissolving them in double the quantity of water (44.8 liters) the osmotic pressure of the solution will be halved. Also, as in the case of a gas, the osmotic pressure of a substance in solution is proportional to the absolute temperature.

The applications of the gas laws to the development of osmotic pressure by substances in solution may be stated as follows.

(1) *Avogadro's Law.* Any two gases of equal volume at a given temperature and pressure contain the same number of molecules. A molecular weight of a gas at 0°C. and 760 mm. Hg pressure occupies a volume of 22.4 liters. So, an amount of substance equal to its molecular weight in grams if dissolved in 22.4 liters of water at a given temperature has an osmotic pressure equal to the pressure which it would exert were it in the gaseous state, namely 760 mm. Hg.

(2) *Boyle's Law.* The osmotic pressure is proportional to the molecular concentration if the temperature remains constant. (See also p. 314.)

(3) *Law of Gay-Lussac.* The osmotic pressure is proportional to the absolute temperature if the molecular concentration be constant.

(4) *Dalton's Law of Partial Pressures.* If several substances are present in a solution, the osmotic pressure exerted by each will be the same as if it were present alone in the solution. In other words, the total osmotic pressure exerted by a solution containing a number of different substances is the sum of the osmotic pressures exerted by each individually.

These laws apply with remarkable precision to dilute solutions, but in the case of concentrated ones, though there is a general agreement with the behavior of gases, other factors enter in which make the applications less perfect. Also substances generally classed as electrolytes (p. 99), sodium chloride for instance, exert osmotic pressures which are much higher than those of non-electrolytes, such as cane sugar or glucose.

This apparent departure from the general principle is due to the fact that each molecule of the electrolyte is split into two parts (ions) and each of these acts as a separate particle and exerts its pressure effect. A sodium chloride solution, therefore, as a result of the dissociation has twice as many active particles as a cane sugar solution even though the number of molecules in a given volume (molecular concentration) of each be the same.

The semipermeability of the membrane, must be emphasized, is an essential factor in the development of osmotic pressure. A solution may possess a very high osmotic pressure when separated from water by a membrane which does not allow the dissolved molecules to pass, but will exhibit no osmotic pressure when separated from water by a membrane perfectly permeable to the substance in solution. Certain membranes, for example the envelope of the red cell, are impermeable to potassium, sodium and calcium, but permeable to water. Others—such as the capillary wall—offer little hindrance to the passage of crystalloids. In the former case, osmotic pressure changes can be brought about within the cell by altering the concentration of sodium chloride in the plasma (p. 48). But in the latter case sodium chloride and other crystalloids, e.g., glucose, urea, bicarbonate, etc., though in the concentrations in which they exist in plasma are capable when placed in an osmometer of developing a pressure of several atmospheres, exert a negligible effect on osmotic pressure within the capillary since the membrane of the latter is fully permeable to them.⁶ The colloid osmotic pressure of the plasma is less than 1 per cent of the total osmotic pressure, i.e., of the osmotic pressure as measured in an osmometer.

Osmotic pressure is one of the fundamental factors underlying many physiological processes in both animal and plant life, e.g., the excretion of urine, the interchange of materials between the interiors of blood cells or tissue cells and their surroundings, the flow of sap in plants, as well as the regulation of blood volume. The fluids of the body contain various electrolytes and organic materials in solution. So permeable membranes of various types possess different selective permeabilities, such as the cell wall, the vascular endothelium, the renal epithelium, the membranes lining the serous cavities and the alimentary tract, are interposed between fluids cap-

⁶ It should be mentioned however that sudden changes in concentration of these substances (as in intravenous injection) will result in temporary disturbances of osmotic relationships while they are diffusing to re-establish equilibrium.

of developing different osmotic pressures. The osmotic pressures are however not constant, but vary from time to time as a result of metabolic processes and the changes in concentration of various constituents of the intracellular and extracellular fluids incident thereto. Furthermore, the permeability of living membranes is not fixed and unalterable but is modified by several factors. Sodium and potassium chlorides, for example, increase membrane permeability to water, the chlorides of calcium and magnesium decrease it; permeability also probably is increased by a rise in temperature and the eggs of various marine forms (*Echinoderm*, *Arbacia* etc.) become more permeable after fertilization. Narcotics, on the other hand, in non-toxic doses decrease the permeability of the cell to water.

ISOTONIC, HYPERTONIC AND HYPOTONIC SOLUTIONS. When two solutions are placed one on either side of a semipermeable membrane and the molecular concentrations of the dissolved substance is such that no osmotic pressure is developed, the solutions are said to be *isotonic*. That is, the pressures on the two sides of the membrane precisely balance one another. When one solution has a higher osmotic pressure than the other it is said to be *hypertonic*; the solution of lower osmotic pressure is termed *hypotonic*.

Hydrostatic pressure

The other important factor in the interchange of fluid between the blood and the general body fluids is the hydrostatic pressure within the capillaries, i.e., the blood pressure, and its relation to that of the extravascular fluids.

The relation of osmotic to hydrostatic pressure in the interchange of fluid across the capillary membrane

It has already been mentioned that the substances in true solution in the plasma, such as glucose, inorganic salts, etc., exert little or no effective osmotic pressure within the capillaries. Their molecules are of such a size that they pass relatively freely through the "pores" of the membrane. Obviously this must be so, otherwise essential nutritive materials could not reach the tissue cells and waste products could not enter the blood stream to be excreted. It is otherwise with the plasma proteins which, owing to the very large size of their molecules, cannot pass readily through the normal capillary wall. The latter is not, however, quite as impermeable to the plasma colloids as has been thought—they "leak" into the extravascular spaces—so, the osmotic pressure which they exert in the vessel is somewhat less than the value obtained in the

laboratory. Since the albumin has the smallest molecule of the three plasma proteins, it escapes through the vessel in relatively greater amounts than the globulin and fibrinogen fractions.

The manner in which these two pressures—osmotic and hydrostatic—act in regulating the interchange of fluids between the tissues and the muscles may now be seen. The blood at the arterial end of a capillary has a pressure, let us say, of 30 mm. Hg. This is a force driving the water and the dissolved crystalloids through the capillary membrane. But the hydrostatic pressure of the tissue fluid on the outer side of the membrane offsets, in part, that within. The pressure of fluid in the tissue spaces is difficult to determine but it is considerably less than that in the capillaries. It probably varies considerably in different regions, being low in those containing much loose areolar tissue. For purposes of illustration let it be assumed to be 8 mm. Hg. The hydrostatic pressure, therefore, which is effective in forcing fluid out of the vessel (filtration pressure) is only the difference between the pressure within and that on the outside of the vessel, that is, 22 mm. Hg. The osmotic (protein or oncotic) pressures of the plasma and tissue fluids must be taken into account, however. In the plasma it amounts to about 25 mm. Hg. The tissue fluids have a lower protein content and consequently a lower osmotic pressure. The latter amounts to about 10 mm. Hg. The difference, i.e., 15 mm. in favor of the plasma will act as an attractive force to hold fluid within the vessels and so should be subtracted from the value of the effective hydrostatic pressure of 22 mm. as calculated above. The net result of these opposing forces will be the filtration of fluid through the vessels under a pressure of $(22 - 15) = 7$ mm. Hg.

Blood		Tissue fluid	
<i>Hydrostatic pressure</i> 30 mm. Hg	Capillary wall	<i>Hydrostatic pressure</i> 8 mm. Hg	
Effective hydrostatic pressure 22 mm. Hg			
<i>Osmotic pressure</i> 25 mm. Hg		Osmotic pressure 10 mm. Hg	
Effective osmotic pressure 15 mm.			
Driving force → 7 mm. Hg			

The osmotic pressure of the plasma, if anything, increases while the blood passes along the capillary as a result of the passage of water outwards and the consequent rise in the concentration of protein. That is, the force holding fluid within the vessel is increased. The hydrostatic pressure, on the other hand, falls gradually from the arterial to the venous end of the capillary. Near the arterial end, the blood pressure being greater than the osmotic pressure, a filtration of fluid

FIG. 10. Illustrating the relation of hydrostatic and osmotic pressures in the regulation of the interchange of fluid between the vessels and the tissue spaces.

with a low concentration of protein will result (see fig. 10). Near the venous end, the hydrostatic pressure falls below the osmotic pressure and a flow of dilute fluid (water and salts) from the tissue spaces into the blood takes place.⁶

⁶ It has been reported by McMaster and Rous that dye particles escape more readily from the venous end of the capillary. They conclude that the capillary permeability increases progressively from the arterial to the venous end. This implies that a steady fall in osmotic pressure would result as the venous end was approached since more protein would leak out.

Transudation of a dilute plasma and reabsorption of a saline fluid, respectively, are continually going on in these two regions of the capillary bed.

Metabolic processes in the tissues bring about changes whereby larger molecules are being broken down into smaller ones; other molecules are removed or built up into larger ones. In this way alterations in molecular concentration and in the diffusibility of the constituents of the tissue fluids with consequent variations in osmotic relationships are occurring ceaselessly.

Under any circumstance in which the blood volume is increased or diminished, either the hydrostatic pressure or the osmotic pressure, both are altered, and it is through such changes that the blood fluid is restored automatically to its previous level. After hemorrhage, for example, the hydrostatic pressure is lowered in the capillary area but the osmotic pressure is unchanged. Fluid will therefore be absorbed from the tissue spaces. Again, when water is drawn from the blood, in consequence of excessive loss of fluid by the kidney, sweat glands or bowels, concentration of the plasma proteins will result. The increased osmotic pressure of the plasma will hasten the rate of absorption from the tissues. The intravenous injection of large quantities of isotonic saline, on the other hand, will have twofold effect of diluting the colloids and temporarily increasing the hydrostatic pressure. The excess fluid in consequence is rapidly eliminated from the blood stream into the tissues and is excreted through the kidney and bowels.

If this conclusion is correct, it is difficult to see how filtration and absorption could occur in different parts of the same capillary and it would be necessary to consider the possibility that filtration occurs in some capillaries and absorption in others.

CHAPTER IV

THE LYMPH AND TISSUE FLUIDS

STRUCTURE OF THE LYMPHATIC SYSTEM

The lymphatic system commences peripherally as a meshwork of delicate vessels (lymph capillaries) which drain the tissue spaces. By the confluence of small vessels larger ones are formed which, receiving tributaries along their course, gradually swell in size, and finally form the right lymphatic and thoracic ducts. These pour their lymph into the blood stream by way of the right and left subclavian veins, respectively. The system is a closed one, its vessels possessing complete walls formed of endothelial cells.¹ But their walls as compared with those of the blood capillaries are extremely permeable; a dye such as T-1824 (Evans blue), which escapes very slowly from the blood stream, passes rapidly from the lymphatic vessels. Small nodes (lymph glands) are interposed in the course of the larger lymph channels. These vessels, upon reaching the gland break up into finer channels, which, plunging into the node, open into the sinuses of its cortex. After passing through the gland the lymph is collected again on the other side by fine vessels which soon re-form into a few larger trunks. The glands are placed at strategic points along the lymph routes, e.g., the elbow and axilla, knee and groin in the case of the upper and lower limbs, and at points in the abdomen, thorax and neck where several lymph vessels become confluent. Lymph vessels are situated in skin, in subcu-

taneous tissue, in the fascial planes of muscles, in the mucosa of the respiratory tract, in the submucosa and subserosa of the gastro-intestinal and genito-urinary tracts and in the capsule and septa of the liver. Those in the intestinal villi are known as *lacteals*. The lymphatic system of the heart consists of intercommunicating plexuses lying beneath the epicardium and the endocardium and within the myocardium. Lymphatics are also present in the areolar tissue underlying the peritoneum and pleurae. They are absent from the central nervous system. In inflammatory states the lymphatics show active proliferation.

FIG. 11. Showing a lymph vessel arising from a vein (redrawn from Sabin).

The skin is supplied richly with lymph capillaries. The cutaneous lymph vessels are so abundant, according to McMaster, that the skin cannot be punctured anywhere without tearing them, and since the flow of lymph along these vessels is relatively rapid, foreign material injected into the skin soon reaches the regional lymph nodes. An injection into the skin is, therefore, an injection into the lymphatic system. The permeability of the lymph capillaries is increased by many agencies, e.g., sunlight, warmth, and mechanical stimulation. Their walls may become so permeable that they can scarcely be considered as channels walled off from the surrounding tissue spaces.

THE NODES AS DEFENSE BARRIERS

The lymph nodes must be looked upon as important structures for the defence of the blood

¹ The lymphatics develop from the endothelium of the veins, appearing in the embryo as offshoots or "buds" from the internal jugular, abdominal and iliac veins (fig. 11). The lymph vessels grow and extend by the proliferation of the endothelial cells composing the walls of these original sprouts. Such reservoirs of fluid as the subarachnoid spaces, the anterior chamber of the eye, the spaces of the internal ear (scala vestibuli and tympani) and the serous cavities (peritoneal and pleural) may be looked upon as belonging to the system of tissue spaces and as having developed from the dilatation and coalescence of smaller preexisting spaces in the mesenchyme. The fluid in the spaces of the central nervous system differs however from lymph and is drained, not by lymphatics, but by special absorbing structures—the arachnoid villi. Nor is the anterior chamber of the eye related to the lymphatics, but is drained through spaces in the pectinate ligament, and the aqueous humor differs in composition from lymph. Fluid is absorbed from the peritoneal cavity mainly via the blood capillaries. Solid particles (e.g., granules), on the other hand, are picked up by large phagocytic cells and conveyed into the lymph system, especially those of the diaphragm.

against the invasion of bacteria or other injurious agents travelling by the lymph paths. When an infection of a part—a finger for instance—lying distal to a gland occurs, the latter becomes inflamed as a result of the localization therein of some of the bacteria or their toxins carried in the lymph. The gland swarms with motile cells (phagocytes) which attack and destroy the invading organisms. In this way a barrier is raised against the passage of deleterious agents, particularly bacteria, into the blood stream. In the case of the limbs at any rate it appears that no material can pass from the tissues to the blood stream via the lymph without filtering through the lymph nodes. The effectiveness of the nodes

THE COMPOSITION OF LYMPH

The lymph of the peripheral (subcutaneous) lymph vessels and the fluid of the tissue spaces are closely similar in composition, and both resemble the blood plasma. They have, however, a protein content which is much lower than that of the blood fluid. Drinker found the protein content to vary under different conditions from 0.3 to 4.0 per cent in mammals. The higher figure, however, is unusual; concentrations between 0.5 and 0.7 per cent were found for human leg lymph. The protein of the tissue fluid (and so of the lymph) is derived, as we have seen, from the blood plasma. The proportion of albumin to globulin (2 to 1) is higher than in plasma as a

as filters has been clearly demonstrated by Drinker and his associates. The popliteal and iliac lymph nodes of dogs were perfused with solutions containing virulent streptococci (250,000,000 colonies per cc.). After perfusion lasting for over an hour the fluid collected from the thoracic duct was found to be sterile. After the node itself has been attacked by the microorganisms it may then serve as a source from which the blood stream becomes infected. Though highly efficient as filters for bacteria the nodes appear to offer but slight hindrance to the passage of viruses. There is evidence that the lymph nodes contribute towards the body's defense in another way, namely, by the production of antibodies.

result of the freer passage of the former protein through the capillary wall. The fibrinogen concentration is very low. Lymph also contains prothrombin (p. 88). It clots slowly. Lymph contains large numbers of white cells, mostly lymphocytes, but very few red cells. The number of leucocytes varies from 1000 to 20,000 per cubic millimeter in thoracic duct lymph of the dog and averages 550 per cubic millimeter in peripheral lymph. Peripheral lymph contains from 300 to 13,000 erythrocytes per cubic millimeter. The lymph flowing from the thoracic duct, since it comes largely from the intestine and liver will vary in composition in accordance with the digestive processes. Its protein content is under

ordinary circumstances from 2 to 4.5 per cent. After a meal of fat the thoracic duct lymph is milky in appearance as a result of its high content in this material. The composition as well as the quantity of lymph varies considerably in different regions and under different experimental conditions which will be considered in the next section. Under ordinary conditions the pressure of the thoracic duct lymph is very low but if the duct is obstructed in the dog, a pressure of 15 cm. of water develops. The *rate of flow* along the human thoracic duct (as measured in cases of duct fistulae) is from 1 to 1.5 cc. per minute. Fat stained with Sudan IV appears in the thoracic duct lymph of man within about 1½ hr. after it has been swallowed. The composition of plasma and peripheral lymph (i.e., lymph in the subcutaneous vessels of the limbs or neck) are compared in table 4.

It will be noted that calcium and total phosphorus, which are in part bound with protein, are in lower concentration than in plasma; the other constituents with the exception of protein and amino acids are in higher concentration.

THE FORMATION OF LYMPH

After what has been said with regard to the forces concerned in the regulation of the fluid interchange between the capillaries and the tissues little need be added in explanation of lymph formation. The two processes are inter-related and similar in nature. Any condition which increases the outpouring of fluid from the capillaries into the tissues will tend to increase the flow of lymph. The lymph capillaries are much more permeable than the blood capillaries, and though the tissue spaces, i.e., the clefts between groups of tissue cells, are separated from the lymphatic system in an anatomical sense, the walls of the latter vessels are so permeable that they offer practically no barrier to either protein or crystalloids. It has been already stated that of the fluid which transudes from the blood at the arterial end of the capillary much of the water is reabsorbed from the venous end. The protein, however, passes into the lymph. The lymph capillary is therefore the special channel whereby protein is returned (in a round about way) to the blood. It is also concerned with the absorption of other colloids, or of particulate matter which may be introduced into the tissue spaces. It is an interesting fact that in the frog, in which the blood capillaries are much more permeable to protein than those of mammals the entire protein

of the plasma passes from the blood and back again to blood via the lymph system, some 50 times in 24 hours (fig. 10).

The mechanism governing the passage of tissue fluid into the lymph vessels is obscure, though the action of the pulse in the blood vessels of the part appears to play a part. McMaster and his associates have demonstrated the importance of a pulsatile flow in the vessels of the perfused rabbit's ear, in the spread of vital dyes through the tissues and in the formation and flow of lymph.

Conditions which increase the lymph flow

(1) INCREASE IN CAPILLARY PRESSURE AS A RESULT OF VENOUS OBSTRUCTION. Landis and Gibbon found that in man filtration from the capillaries showed a definite increase when the venous pressure rose above 12 or 15 cm. of water. The rate of filtration from the capillaries was directly proportional to the increase in venous pressure (fig. 12). At a given venous pressure the filtration rate increased rapidly at first but gradually slowed and finally ceased. This falling off in the filtration rate is ascribed to the rise in extracapillary pressure, due to the fluid accumulation, which opposes the hydrostatic pressure within the capillary.

Increased pressure in the veins of the portal area, as may be produced by obstructing the portal vein or the hepatic veins, causes increased filtration into the tissues of the abdominal viscera and a great increase in the volume of lymph flowing along the thoracic duct.

Increase in arterial pressure, on the other hand, does not increase filtration in animals until the pressure reaches around 300 mm. Hg.

(2) INCREASED PERMEABILITY OF THE CAPILLARY WALL. (a) *A rise in temperature* increases capillary permeability, raises the filtration rate and the flow of lymph.

(b) *Capillary poisons*. *Peptone* increases the flow of lymph from the thoracic duct probably as a result of its injurious effect upon the abdominal capillaries. The increased flow occurs after removal of the liver so injury to the vessels of this organ is not essential as was once believed (Markowitz and Mann). Other substances which increase lymph flow in this way are, extracts of strawberries, cray-fish, mussels and leeches; histamine and foreign proteins. Such materials are referred to by Heidenhain, as *lymphagogues of the first class*. Heidenhain held the view which is held no longer that the endothelium of the capillary possessed a true secretory function and

that it was stimulated to activity by lymphagogenic agents.

(c) *Reduced oxygen supply* to the tissues (oxygen want), probably through damage to the capillary endothelium.

(3) **HYPERTONIC SOLUTIONS.** The intravenous injection of a concentrated solution of glucose, sodium sulphate or sodium chloride causes an increased flow of lymph from the thoracic duct in the following manner. These substances in

FIG. 12. Showing rates of filtration produced during 30 minutes by venous pressures between 20 and 80 cm. water (after Landis and Gibbon).

concentrated solution though they permeate the capillary wall exert an osmotic pressure until equilibrium between the extravascular and intravascular fluids is re-established. Fluid is "attracted" from the tissue spaces, particularly of the muscles and subcutaneous tissues of the limbs, which in consequence show a fall in volume; the brain shrinks. The removal of fluid may actually extend to the fluids within the cells which undergo shrinkage; and general desiccation of the tissues result (p. 17). The blood volume for

the time is greatly augmented, the excess fluid, for the most part being accommodated in the capacious capillary and venous areas of the abdomen. The viscera—liver, kidneys, spleen and intestines—increase in volume, due to the distension of their vascular beds, and a great outpouring of fluid occurs, which swells the volume of lymph in the thoracic duct. In this way these substances produce a redistribution of fluid. Since the water-logged tissues eventually give up the extra fluid for excretion the body suffers a net loss.

The injection of isotonic saline will also increase the lymph flow since the plasma colloids are diluted thereby and the filtration through the capillary is increased. Substances which increase the flow of lymph in the manner described in this section are sometimes spoken of as *lymphagogues of the second class*.

The effect which hypertonic solutions have upon the movement of tissue fluids had extensive application during the first World War. Sir A. E. Wright introduced the practice of packing wounds with salt crystals or irrigating them with a hypertonic salt solution. This causes an outward flow of lymph and tissue fluid, which results in the mechanical removal of the bacteria and their toxins from the tissues bordering the wound.

(4) **INCREASED FUNCTIONAL ACTIVITY.** When a gland or muscle enters into activity an increase in lymph flow occurs which starts a little after the commencement of the secretory or contractile response, but is nearly synchronous with the increased metabolism resulting from the activity. The increased flow is ascribed to (a) formation of metabolites which increase the osmotic pressure of the tissue fluids and so "attract" more fluid from the vessels (b) vasodilation and increased capillary pressure.

During rest the flow along the lymph vessels of the muscles and subcutaneous tissues is slight, and the protein content of the lymph is high. During activity the protein concentrations fall since less transuded water undergoes reabsorption into the blood and more is carried away by the lymph channels. The contracting muscles exert a pumping effect upon the lymph, driving it along the vessels.

(5) **MASSAGE AND PASSIVE MOVEMENT** act to a certain extent like muscular activity. They augment the blood flow and capillary pressure and so increase lymph formation. The manipulations and movements of the muscles serve to propel the lymph along the lymphatic channels.

EDEMA (SEE ALSO P. 406)

Edema is the term applied to an excessive accumulation of fluids in the tissue spaces, and is due to a disturbance in the mechanisms of fluid interchange, which have been considered in the preceding pages.² Instead of there being a perfect balance struck between the inward and outward flow of fluid through the capillary membrane absorption is exceeded by transudation. The particular factor or factors of the mechanism that are disordered are not always clear, and a satisfactory explanation of all forms of edema cannot be given. But from previous discussions it is evident that edema may arise from (1) Reduction in the osmotic pressure of the plasma, i.e., in protein concentration. (2) General or localized changes in capillary blood pressure. (3) Increased permeability of the capillary membrane. (4) Obstruction of the lymph channels. There is a tendency for edema to reach a certain degree and then become stationary provided the conditions producing it remain constant, for as we have seen, when the tissue fluid pressure reaches a critical level its opposition to the force driving fluid from the vessels prevents further transudation.

Since edema is only a symptom of some primary condition it may have a variety of causes, according to the particular disease with which it is associated.

(1) *Cardiac edema.* This is due mainly to the slowing of the peripheral blood flow and the resulting rise in capillary pressure. The increased venous pressure and the distension of vessels in the capillary areas will be greatest in dependent parts of the body, and it is here that the edema of cardiac failure usually first makes its appearance.

² When the subcutaneous tissues are involved these appear swollen, and leave the imprint of the thumb when it is pressed into the skin (pitting). Dropsy (hydrops) is an old-fashioned term which is applied to edema as defined above or to a free collection of fluid within one of the body cavities, e.g., the thorax or the abdomen. *Hydrothorax* is also applied to the former of these conditions and *ascites* to the latter. *Anasarca* is a more or less generalized edema involving the subcutaneous tissues.

It is important to remember that the term edema applies to a gross collection of extravascular fluid. The bulk of tissue fluid fluctuates widely in health, and in pathological states may be very considerably increased before the increase is evident clinically. When, for example, a normal person stands for a time the extravascular fluid of the legs increases; and the immersion of a limb in a hot bath hastens the rate at which fluid transudes from the vessels—the limb volume rises as a result, largely, of fluid accumulation in the tissues. Drury and Jones found that edema appeared when the increase in fluid increased the volume of the leg by 8 per cent.

Collection of fluid in the peritoneal or the pleural cavity also commonly occurs. Edema commences when the capillary blood pressure rises to within 2 mm. Hg of the osmotic pressure of the plasma. In some cases, reduction in plasma protein concentration is also a factor in cardiac edema.

Damage and increased permeability of the capillary membrane due to deficiency in the oxygen supply to the tissues (stagnant type of anoxia, p. 359) may be a contributory cause.

(2) *Mechanical obstruction of veins.* When the main veins leading from a part are obstructed by new growth, fibrous tissue, as in cirrhosis of the liver, thrombosis, etc., increased transudation of fluid occurs. This is due in part to the rise in intracapillary pressure but the permeability of the capillary wall is also increased as a result of the impaired blood supply or, as in the case of new growth, probably to the production of toxic substances as well.

(3) *Edema due to renal disease.* In chronic glomerulo-nephritis and in nephrosis the edema is due to the reduction in the concentration of the plasma proteins and so of the osmotic pressure of the blood (see p. 23). In acute nephritis the capillary wall is damaged and its permeability increased, protein escapes in excessive amounts into the tissues, so the edema fluid has a relatively high protein concentration.

(4) *Inflammatory edema.* In this type several factors combine to produce the fluid infiltration of the tissues. Increased capillary pressure occurs, due to dilatation of the vessels and local slowing of the blood stream (p. 114) as well as to thrombosis and obstruction of the returning veins. The lymphatics for a variable distance from the inflammatory area are obstructed as well. The capillary walls are also seriously damaged by the bacterial toxin or other injurious agent, so that a fluid with a high protein content escapes from the vessels. The edema is localized to an area of varying extent surrounding the injured site.

(5) *Giant edema.* This is a localized non-inflammatory edema which comes on with great rapidity and involves the loose areolar tissue in such regions as the hands, face, genitalia or larynx. It occasionally runs in families. Little is known definitely regarding the mode of its production. A histamine-like substance liberated at the site of the edema is apparently the immediate cause (p. 269). The remote exciting cause is frequently a foreign protein consumed in the diet which apparently gains access to the blood stream in a more or less unchanged state, for the attack often follows a particular food to which the subject is sus-

ceptible, and is sometimes accompanied by gastrointestinal disturbances. The effects are therefore of an anaphylactic nature and constitute one type of allergy. This type, also termed *angioneurotic edema*, is allied to the very localized edemas which constitute the condition known as urticaria and which as suggested by Lewis are due to the liberation of a histamine-like substance in the skin.

(6) *Edema due to malnutrition or to toxic substances.* Edema may occur in the anemias or in conditions in which the general nutrition of the body suffers. When the diet is deficient in vitamins, or there is too little fat or protein in the diet edema may occur, as in beriberi, scurvy, "war edema" or in the faulty nutrition of infants. In animals edematous conditions have actually been induced by general underfeeding, or by a diet deficient in fat and in fat soluble vitamins, or by one deficient in protein alone. The factors responsible for the increased transudation in these cases are not always clear, but in others there is a marked lowering of plasma protein which alone is sufficient to account for the development of the condition. Changes in the capillary membrane as a result of impaired nutrition, or due to the direct action of toxic substances are indicated in some cases.

Certain chemical substances such as arsenic, salts of heavy metals, and the toxins of certain infectious diseases, such as diphtheria, acute nephritis, etc., are known to act as capillary poisons and apparently cause edema in this way. An interesting type of a toxic edema is that which may be produced in animals by the injection of hematoporphyrin (p. 46). This substance appears to sensitize the tissues towards light rays, and the edema occurs only after exposure.

Histamine causes local edema at the point of injection by inducing capillary dilatation and increased permeability of the membrane (p. 269).

(7) *Edema due to lymphatic obstruction.* Obstruction to the outflow of lymph from the tissue spaces may cause pronounced edema, even though the venous channels and the capillary vessels are unaffected. Edema of this nature is readily produced in frogs by compression of the lymph channels alone. It is more difficult to produce edema in this way in higher animals but if the obstruction is complete edema also occurs in these also. Edema of this nature is seen in infections with the filarial parasite which finds its way into the lymph vessels of the limbs and blocks their lumen with the production of the condition known as elephantiasis. The pleural cavities depend for the absorption of a fluid upon the lymph channels, and accumulations of fluid may occur here as a result of lymphatic obstruction. The edema associated with carcinoma is due chiefly to the filling of the lymphatic channels with cords of cancer cells as well as to venous obstruction caused by the pressure of the growth. The "milk leg" of the puerperium is in part due to lymphatic obstruction.

(8) *Heat edema.* The effect of heat upon capillary permeability has been mentioned (p. 29). Excessive heat may actually lead to edema in man. It occurs in the tropics and occasionally in temperate (so-called) zones during an intense heat wave. Increase in blood volume, enlargement of the filtering surface as a result of the opening up of fresh capillaries and the rise in capillary pressure incident to the dilatation of capillaries previously patent, are also factors in the production of this type of edema.

CHAPTER V

TRANSFUSION

The materials employed for restoring the blood volume to normal are; (1) *Whole blood*, (2) *plasma or serum*, (3) *solutions of colloids*, e.g., gum acacia, isinglass etc., (4) *solutions of crystalloids*, e.g., saline or glucose solutions.

(1) WHOLE BLOOD¹

Theoretically, whole human blood is, of course, the ideal transfusion fluid. The improvements and simplification of technique in recent years and the advance in knowledge of blood incompatibilities have made blood transfusion immeasurably safer, and rendered it available under circumstances which hitherto would have been insuperable. It is not only in cases of emergency such as severe hemorrhage or wound shock, but in several other conditions that it is used today. Below are listed some of the conditions in which it is employed.

Hemorrhage.

Hemorrhagic diseases, e.g., hemophilia, purpura hemorrhagica, anemias and leucemias.

Shock (wounds, burns).

Malnutrition in infants, marasmus, acute intoxications.

Septic conditions, septicemias.

The red cells of the transfused blood survive and carry out their functions for several days after their injection. On this account whole blood is greatly superior to any other transfusion fluid

¹ Within recent years stored blood (or plasma) is being used to an ever increasing extent. Blood collected from the dead has been employed in Russia, but cadaver blood for obvious reasons, has not found general favor. Placental blood or blood removed by venesection from cases of congestive heart failure may be employed, but the blood of healthy donors is preferable. The blood is preserved at a temperature of around 1°C. after dilution with a citrate-dextrose mixture in the proportions of 5 parts of blood, 1 part of 3.2% citrate solution and 6.5 parts of 5.4% dextrose solution. Kept in this way blood remains suitable for transfusion for twenty days, perhaps longer. It was found, however, by Belk and Barnes that the survival time of the red cells after transfusion was very short (24-48 hours) if the blood had been stored for more than 2 or 3 days. Others find, however, that most of the cells of the preserved blood survive for a longer period than this. These so-called *blood banks* have the advantage that a quantity of blood already prepared for transfusion can be obtained at a moment's notice. But there is also the great disadvantage that any blood not used within ten days or so must be discarded.

in any condition in which the respiratory area of the blood has been greatly reduced, e.g., very severe hemorrhage or hemorrhage in an anemic person, CO poisoning, etc. It is also more effective in traumatic shock than plasma, serum or other blood substitutes. According to Ashby, from 60 to 80 per cent of the donated cells live for over 30 days. Fifty per cent were detectable in some cases after more than 45 days. The use of blood as a transfusion fluid, nevertheless, is hedged about by hazards both to the recipient and to some extent to the donor. On this account it is a suitable method only when adequate facilities for guarding against these dangers are available, otherwise some blood substitute will have to be resorted to. The safeguards which must be taken are:

(a) The donor must be healthy. Several cases have been reported of disease having been transmitted by the transfused blood. Syphilis malaria and acute diseases have been reported to have followed blood transfusion. In some instances the transmission in the transfused blood of a particular foreign protein of dietary origin, to which the recipient but not the donor is sensitive, has caused an allergic reaction.

(b) A too rapid transfusion of blood is dangerous, especially in children or undersized persons, for the sudden increase in circulating fluid may cause serious embarrassment to the right side of the heart. In an adult, the usual transfusion rate is from 100 to 200 cc. per hour, but one of 20 cc. or less causes little cardiovascular effect, even though the blood volume is considerably increased. At higher rates, the venous pressure rises and the cardiac output increases. Rapid infusions of fluid into animals causes death from cardiac failure, preceded by an inordinate rise in venous pressure and pulmonary edema. The total quantity injected varies according to circumstances and the size of the patient, from about 500 to 1500 cc. or more.

(c) An ever present potential danger is that of incompatibility. The donor's blood must always be tested for its compatibility with the blood of the recipient. Normal plasma contains substances which have the power to cause the clumping together (agglutination) and subsequent disintegration (hemolysis) of the foreign corpuscles of another

species. Agglutination may also result when the bloods of two human individuals are mixed. The bloods are then said to be incompatible and transfusion under such circumstances will lead to very serious if not fatal results (p. 35).

THE BLOOD GROUPS

As a result of the work of several investigators in the early years of this century, notably that of Landsteiner, of Jansky and of Moss, it has been established that the blood of any person falls into one or other of four well defined groups, according to its agglutinating reactions. These groups were originally designated by the Roman

TABLE 5
Jansky's classification of blood groups

CORPUSCLES	SERUM			
	O	A	B	AB
O (I)	-	-	-	-
A (II)	+	-	+	-
B (III)	+	+	-	-
AB (IV)	+	+	+	-

+ means agglutination; - means no agglutination.

Group O. The serum of which agglutinates the corpuscles of the other three groups. The corpuscles of this group are not agglutinated by any serum.

Group A. The serum agglutinates the corpuscles of Groups B and AB, but not those of Groups O and A. The corpuscles are agglutinated by the serum of Groups O or B, but not by that of Groups A and AB.

Group B. The serum agglutinates the cells of Groups A and AB, but not those of Groups O and B. The corpuscles are agglutinated by the serum of Groups O or A, but not by that of Groups B and AB.

Group AB. The serum of this group does not agglutinate any corpuscles. The corpuscles are agglutinated by the serum of all other Groups.

numerals I, II, III and IV, respectively, but are now referred to by the letters O, A, B and AB (see p. 36). According to the classification of Jansky (1907) which is most commonly employed, and which out of respect for its priority has been recommended by a committee of the American Bacteriological Society, the groups exhibit the reactions shown in table 5.

About 43 per cent of all individuals of Western races belong to Group O and 40 per cent to Group A. Thirteen per cent and 4 per cent belong to Groups B and AB, respectively.

The alternative classification of Moss (1910) is sometimes employed. In this, Group O corre-

sponds to Jansky's Group AB, and Group AB to Jansky's Group O.

Consultation with the table will show that the serum of Group AB (vertical row on extreme right) is compatible with the corpuscles of all the other groups, i.e., no agglutination of the corpuscles of any donor should occur when the recipient belongs to this group. It will be noted however, that the cells of Group AB (lowest horizontal row) are agglutinated by the sera of all the other groups when tested outside the body. It might therefore be thought that this reaction could occur in the blood of the recipient but as a matter of fact, when a patient belonging to Group AB is transfused with the blood of any other group, agglutination of his (patient's) corpuscles does not usually occur. The reason for this is not clear, unless it is that the serum of the injected blood is so highly diluted by the patient's serum. It is said however, that if the donor's serum be diluted to the same degree as occurs when it is transfused and is then mixed with the cells of group AB outside the body, agglutination does occur. Whatever the explanation, the fact remains that the reaction of the donor's corpuscles to the serum of the recipient is the important factor to consider, and that the agglutinating property of the donor's serum is not generally evident. On this account members of Group AB are sometimes spoken of as "universal recipients."

It will be seen from the table that the corpuscles of Group O (uppermost horizontal row) are not agglutinated by any serum. Members of this group are therefore called "universal donors" since agglutination does not, as a rule, occur when this blood is transfused into a member of any of the other groups.

The terms "universal donor" and "universal recipient" though in general use are dangerously misleading. Severe and even fatal reactions may occasionally result from the transfusion of blood of group O into a subject of one of the other groups. Similarly, it cannot be taken for granted that a subject of group AB can be transfused with impunity with the blood from any of the other groups. Such procedures are especially hazardous in the case of children, probably for the reason that they are transfused with relatively large quantities of blood than are adults; the donor's blood, in consequence, is in relatively high concentration in the recipient's blood stream. Therefore, blood of the same group to which the recipient belongs should always be employed, unless it

unobtainable and the emergency does not brook delay.

Determination of the group to which a particular blood sample belongs

In order to determine the particular group to which a given sample of blood belongs, it is not necessary to have sera of each group, but only of Groups A and B. Sealed tubes containing high titer sera of these two groups are kept on hand for testing purposes. Reference to tables 5 and 6 and to figure 13 will show the reason for this. If a diluted specimen of the unknown blood is agglutinated neither by Group A or Group B serum, it must belong to Group O. If it reacts to Group B serum but not to Group A, it must belong to Group A, and similarly, if it reacts to Group A but not to Group B, it belongs to Group B. If it is agglutinated by both test sera, it belongs to Group AB. To perform the test a

TABLE 6

+ = agglutination; - = no agglutination.

drop each of Group A and Group B sera are placed side by side upon a white opal glass tile which has been slightly warmed. A specimen of blood from the person whose blood group is being determined is mixed with a 0.9 per cent solution of sodium chloride to make a 2 to 5 dilution. A drop of the diluted blood is added to each sample of test serum.

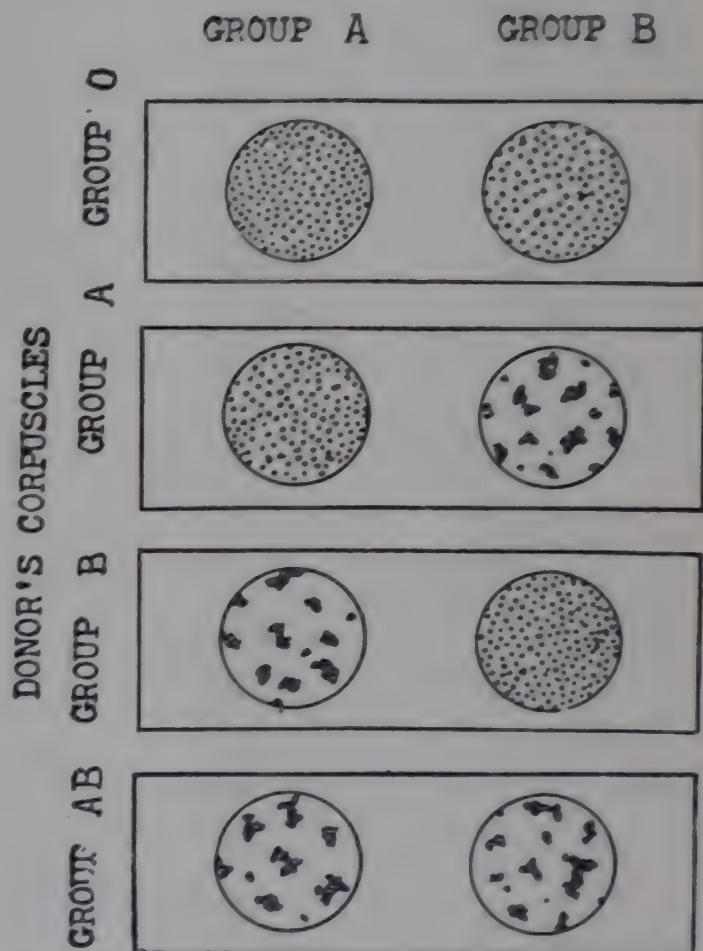

Agglutination, if it occurs, is usually visible under the microscope within a few minutes or may be seen with the naked eye, the clumped corpuscles appearing like grains of cayenne pepper upon a clear fluid. The reaction, however, may be delayed for as long as 20 minutes. In the absence of agglutination the fluid remains uniformly pink. Lists of donors, classified in respect to the groups to which they belong, are usually kept in large clinics so that the appropriate blood can be obtained quickly in an emergency. Cross or direct matching also should be carried out as an additional check. A diluted specimen of the recipient's blood is mixed with a sample of the

donor's serum, and a similar sample of the donor's blood with the patient's serum. The mixtures are observed microscopically for agglutination.

The effects of the transfusion of incompatible blood

The most urgent symptoms develop. Among these are tingling pains shooting through the body, severe lumbar pain, precordial distress, cyanosis, rapid thready pulse and other manifestations of severe collapse which frequently end fatally. Hemoglobin

TEST SERA

appears in the urine almost invariably. Symptoms are due, in part at least, to the mechanical effect of the agglutinated corpuscles, which cause the blockage of small vessels in vital regions. Later, hemolysis of the agglutinated cells occurs. In fatal cases the tubules of the kidneys have been found blocked with hematin produced by the action of the acid urine upon the hemoglobin liberated from the broken down erythrocytes. Suppression of urine preceded death. When an accident, due to the transfusion of incompatible blood, threatens, an attempt is made to prevent the deposition of pigment in the tubules by rendering the urine alkaline. In some cases the symptoms are

of an anaphylactic nature due to the protein of the foreign serum rather than to any agglutinating reaction, and occur after the later transfusions of a series from the same donor. Minor reactions which are not easy to explain sometimes occur even when the bloods appear by the usual tests to be compatible. (See also p. 37).

The exceptions to the rule are shown in heavy type. They are probably due to illegitimacy.

TABLE 7½
Showing the presence in the various groups of agglutinogens and agglutinins (Tansky)

GROUP	CELLS CONTAIN ISO-AGGLUTINOGENS	SERUM CONTAINS ISO-AGGLUTININS
O	O (neither)	α and β
A	A	β
B	B	α
AB	A and B	o (neither)

Agglutination occurs only when corresponding iso-agglutinins and iso-agglutinogens are brought into contact, as would be the case were Group B serum mixed with Group A cells. Obviously such a combination does not exist in the blood of any individual, otherwise auto-agglutination would occur.

Theory of blood grouping

Landsteiner postulated the existence of two specific substances in serum which he called *iso-agglutinins*, and two substances in the corpuscles which he termed *iso-agglutinogens*. The former may be represented by the Greek letters α and β; the latter by the capitals A and B. A given serum might contain one, both or

neither iso-agglutinin. Similarly the corpuscles may contain one, both or neither iso-agglutinin (table 7½). In order for agglutination to occur when two bloods are mixed α must be present with A (αA) or β with B (βB). If o be used to represent the absence of the two iso-agglutinins and O the absence of the two iso-agglutinogens then the four groups may be designated as follows:

Group O. The corpuscles have no iso-agglutinin (O); the serum has α and β iso-agglutinins. This group may therefore be designated Oαβ. Its corpuscles obviously cannot be agglutinated by any serum but its serum will agglutinate any corpuscles containing A or B, i.e., the corpuscles of any of the other groups.
Group A. Corpuscles have A; serum has β. This group may therefore be represented by Aβ. Its corpuscles are agglutinated by any serum containing α; its serum agglutinates corpuscles containing B.
Group B. Corpuscles have B and serum has α. The group is represented by Bα. The corpuscles are agglutinated by a serum containing β and the serum agglutinates corpuscles containing A.
Group AB. Corpuscles have A and B but serum has no iso-agglutinins. The group is represented by ABo. Obviously the corpuscles are agglutinated by any of the other sera, but the serum of this group will not agglutinate the corpuscles of any other group.

It is owing to the confusion which has arisen from the existence of two classifications, Jansky and Moss, that the system has been adopted whereby the blood groups are referred to by the letters indicating their serological characteristics, namely Oαβ, AB etc., or simply by letters showing the characteristics of the corpuscles, that is, O, A, B and AB.

Hereditary transmission of the blood groups

It is sometimes thought that close relatives must have compatible bloods, and that consequently a child could be transfused without harm with the mother's blood. The placenta, however, offers a barrier to the passage of the serological characters of the maternal blood into the blood of the fetus. It is true, on the other hand, that the iso-agglutinins are established much later after birth than the iso-agglutinogens, and may be in very low concentration in the new-born (whose blood would therefore correspond to Group AB). It has therefore been suggested that the mother's blood no matter to what group it belonged would not undergo agglutination when transfused into the baby; but this is a decidedly dangerous assumption, for iso-agglutinins are not always in low concentration at birth.
The blood once established in its group remains unchanged throughout life. Even after a large number of transfusions, blood retains its original serological characters.

The agglutinability of the corpuscles of the different groups is inherited as independent pairs of factors. Group A is due to the inheritance of iso-agglutinin A and iso-agglutinin β . The iso-agglutinin is a dominant factor, the iso-agglutinin is recessive. We may therefore refer to the character of this group as A. Group B depends upon the inheritance of the iso-agglutinin B. The character of this group may be referred to therefore as B.

There are therefore two dominant factors, A and B, and two recessive factors, α and β . The letter O is used to represent the absence of both dominants A and B. Since this means that the recessives alone are present, O will simply stand for the recessive characters. If neither parent possesses a dominant factor, i.e., they both belong to Group O (I), the child obviously cannot receive either A or B and so must also belong to Group O. If one parent possess only one dominant, say A, the other only B, then the child may receive A from one and B from the other and so belong to Group AB (IV). But since the parents must also each possess a hidden (recessive) factor, the child may inherit α from one and β from the other and so belong to Group O (I). Or it may receive an A or a B together with a β or an α , and so belong to Group A (II) or B (III) respectively. Again, if one parent is an AB, the other A or B, the child could not be of Group O since it would under any circumstances receive at least one dominant factor. It might belong to Group A, B or AB, depending upon chance. The possible parental combinations and the proportion of the children which will fall into each group for any given combination are shown in table 7 from Lattes.

Subgroups. The main blood group A is made up of the subgroups A_1 and A_2 , and the main group AB of the subgroups A_1B and A_2B . This is because the cells of both these groups may contain one or other of two types of agglutinogens which have been designated A_1 and A_2 . About 75 per cent of persons belonging to group A are included in subgroup A_1 and about 20 per cent in subgroup A_2 . In rare instances, the agglutinin α_2 is present in the plasmas of subgroups A_1 and A_1B and agglutinin α_1 in the plasmas of subgroups A_2 and A_2B . The main group O (universal donor, so-called) may also, though very rarely, contain the α_1 agglutinin. Should the plasma of a donor contain α_1 agglutinin (anti- A_1) in high titer and the recipient belong to subgroup A_1 or A_1B a reaction will occur. Similarly, α_2 plasma will be incompatible with A_2 or A_2B cells. The subgroups and the distribution of the agglutinogens and agglutinins are shown in the table below.

The Rh factor. Landsteiner and Wiener reported the discovery of an agglutinin which they named the *Rh factor*, because it is present in

Rhesus monkey blood as well as in human blood in 85 per cent of white persons.² Should a donor whose blood contains the Rh factor be transfused into a patient whose blood does not contain it, an anti-Rh agglutinin is developed in the recipient's blood. The anti-Rh agglutinin develops within 12 days following the transfusion, and if a second transfusion should be given to such a patient after this period a hemolytic reaction due to the action of the anti-Rh factor results. A hemolytic reaction caused by this factor may follow a single transfusion in pregnant women or post-partum, which is thought to be due to the anti-Rh agglutinin formed in the mother's blood as a result of the blood of the fetus containing the Rh factor inherited from the father.

BLOOD GROUPS	AGGLUTINOGENS (IN CELLS)	AGGLUTININS (IN PLASMA)
O	None	α and β (rarely α_1)
A $\left\{ \begin{matrix} A_1 \\ A_2 \end{matrix} \right.$	A_1	β (rarely α_2)
B	A_2	β (rarely α_1)
AB $\left\{ \begin{matrix} A_1 \\ A_2 \end{matrix} \right.$	B	α
	A_1 and B	None (rarely α_2)
	A_2 and B	None (rarely α_1)

A fatal blood disorder of the new-born, known as *erythroblastosis fetalis*, is believed to be due to the production of an anti-Rh agglutinin in the mother's blood which crosses the placental barrier and causes destruction of the red cells of the fetus whose blood, in 90 per cent of cases of this disease, is Rh positive.

Other agglutinogens, designated M and N, have been discovered more recently. Approximately 45 per cent of white persons have both M and N agglutinogens. The remaining 55 per cent have either M or N, most frequently the former. The plasma normally contains no antibodies (agglutinins) for these factors, but an anti-M or an anti-N agglutinin may develop in the blood of the recipient if he has been transfused repeatedly with blood from a donor belonging to the other subgroup. A reaction is not likely to occur, however, since the agglutinin is rarely, if ever, of sufficiently high titer to cause agglutination.

(2) HUMAN SERUM AND PLASMA

Many of the drawbacks inherent in the use of whole blood for transfusion are obviated by substituting human serum or plasma. These blood

² This percentage does not hold true for certain races, e.g. American Indians.

derivatives when pooled from a number of donors can be transfused indiscriminately without regard for the blood groups. Furthermore, liquid plasma or serum if collected under strictly sterile conditions can be stored under refrigeration for an indefinite period. Plasma kept in the frozen state is highly recommended by Strumia and McGraw as being safer than storage in liquid form. Plasma or serum dried *in vacuo* from the frozen state by the *desivac process* of Flosdorf, Stokes and Mudd is the preparation *par excellence*, especially for use in the armed services. It can be stored without refrigeration, is easily transported and the dangers of bacterial contamination or of deterioration are at a minimum. When required for use, distilled water, equal in volume to that which had been removed in the drying process, is added.

(3) SOLUTIONS OF COLLOIDS

The limited availability of whole human blood or of its derivatives, plasma or serum, has inspired a search for a blood substitute which would resemble as closely as possible the physical properties of plasma. The requirements of an artificial transfusion material are several. (a) The molecules (or particles) of the substance must be of such a size that its solution will not leave the circulation too freely. (b) The solution must have an osmotic pressure and a viscosity approaching as closely as possible these properties of whole blood: such qualifications depend upon molecular size and shape. (c) It should be isotonic with the contents of the corpuscles. (d) It must, of course, be non-toxic and innocuous in every respect. (e) It should not hinder plasma protein production. In addition, the material should be readily available in large quantities, preferably cheap, capable of being sterilized by simple means, and of being quickly prepared for use. Provided a material is suitable for transfusion in the foregoing respects there appears to be no valid objection to the use of some fluid other than blood or its derivatives to fill the vessels after hemorrhage. The properties which render a fluid suitable for transfusion are physical rather than chemical. Blood apparently possesses no advantage by virtue of any biochemical characteristics which it possesses.

Gum acacia in a 6 per cent solution in saline was introduced by Bayliss as a transfusion fluid during the first World War and proved highly successful. The osmotic pressure and viscosity of this solution closely resemble those of plasma.

The molecules of *gum acacia* aggregate into particles comparable in size to those of the plasma proteins and do not escape freely through the capillary membrane.

However, experience since the first world war has revealed some undesirable features of *gum acacia*. *Gum acacia* is a polysaccharide which the body cannot metabolize. It, like other foreign materials which cannot be disposed of in other ways, is taken up by the reticulo-endothelial elements of the liver and elsewhere. The liver may become greatly enlarged after repeated transfusions with this material and sometimes shows areas of necrosis. The hepatic function of producing plasma protein is seriously depressed; the concentration of protein in the plasma is lowered following large transfusions of *gum acacia* and may remain below normal for a considerable time after this blood substitute has been administered.

Isinglass (collagen prepared from the swim-bladders of certain species of fish, e.g., sturgeon, hake, etc.) has been advocated by Taylor and Waters, in a concentration of 6 per cent in physiological saline, as a blood substitute. Such a solution fulfills the requirements of a blood substitute listed above. It has been used clinically and offers much promise as a blood substitute. It is free from anaphylactic or pyrogenic reactions. The molecular weight of *isinglass*, after autoclaving, is between 18,000 and 30,000.

Animal gelatin, which is closely similar to *isinglass* chemically, has been used clinically with satisfactory results.

Pectin, a hemicellulose (consisting of partially methylated galacturonic acid anhydride units) which is obtained from citrus and other fruits and used domestically as a jellying agent, has been employed by Hartman and his associates.

Other transfusion materials which are being subjected to animal experimentation are *hemoglobin-Ringer* solution, under investigation by Amberson and his colleagues, and *human and beef albumin* by Cohn, Janeway and associates. The reader interested in this subject is referred to the original papers.

(4) SOLUTIONS OF CRYSTALLOIDS

The small molecules of salt or of glucose pass freely through the capillary wall. They exert a negligible osmotic effect; the injected fluid is therefore not retained in the circulation. For this reason such fluids though capable of raising the blood pressure temporarily are quite unable

to maintain it for any considerable length of time. Indeed they may do serious harm, for the transfused fluid as it leaks into the tissues carries plasma protein with it. This is particularly likely to occur in the case of saline. Transudation of fluid into the tissue of the lung—pulmonary edema—may result. When, on the other hand, dehydration of the tissues and loss of blood *water*, as shown by the concentration of the plasma proteins, are prominent features, then the subcu-

taneous or intravenous injection of saline (with the addition of glucose) or water by mouth, would appear, from physiological principles, to be a logical procedure. In the dehydration resulting from chloride depletion (p. 18) sodium chloride is clearly indicated. A solution of this salt serves not only to supply fluid but to replenish the base the loss of which is such an important factor in the development of the dehydrated state.

CHAPTER VI

HEMOGLOBIN

Hemoglobin is the coloring matter of the erythrocytes, and the chief function of the red cell is to store this pigment and carry it around the circulation. About 10 grams of hemoglobin pass through the lungs per second. It takes up a comparatively large load of oxygen which it carries to the tissues. One hundred cubic centimeters of water at the temperature of the body and exposed to an oxygen pressure of 100 mm. Hg absorbs a third of a cubic centimeter of the gas. One hundred cubic centimeters of blood, on the other hand, at the same temperature and pressure will take up about 20.0 cc.,—that is, 60 times more. The difference is due to the hemoglobin. The total amount of blood in the human body will hold approximately 1200 cc. of oxygen (200 cc. per liter of blood). This quantity of oxygen is used by the tissues in 5 minutes or so during rest and in a fraction of a minute during muscular exertion. In the absence of hemoglobin, the entire duty for the carriage of oxygen would have to be performed by the plasma, and in order that this should be able to absorb the necessary amount of gas, it would have to be increased at least 60 times in amount. As pointed out by Barcroft, the circulating fluid, instead of being about 6 liters or $\frac{1}{11}$ of the body weight, would then need to be over 350 liters. That is, more than five times the bulk of the solid tissues.

THE CHEMICAL CONSTITUTION OF HEMOGLOBIN. THE "STONES" FROM WHICH ITS MOLECULE IS BUILT

Hemoglobin is a conjugated protein consisting of an iron-containing pigment portion combined with a protein of the histone class called *globin*. The hemoglobin complex when its globin is in the natural state, forms a loose combination with oxygen (oxygenation)—the iron being in the ferrous state (Fe^{++}). Under certain abnormal conditions it forms a stable compound with oxygen (oxidation, i.e., the production of a true oxide)—the iron being in the ferric state (Fe^{+++}). A more detailed consideration of hemoglobin structure follows.

PORPHYRINS are pigments which either alone or as the basis of more complex compounds are found throughout plant and animal life from the highest

to the lowest forms. A porphyrin is the pigment basis of chlorophyll—the green coloring matter of plants. One is found as a brown pigment in the shells of many eggs, and also in the dark line running down the back of the earthworm. On the other hand, when conjugated with other substances porphyrins are the basis of the blood and tissue pigments of various animals.

The porphyrin molecule is constituted of four pyrrol nuclei. The pyrrol nucleus has the following structure:

Four of these rings joined together constitute porphyrin. The manner in which the rings are connected may be seen in the following formula.

Aetioporphyrin ($\text{C}_{22}\text{H}_{30}\text{N}_4$)

This represents a porphyrin in its simplest state (*aetioporphyrin*) or rather the common nucleus of several porphyrins, for there are many different varieties. The distinctive characters of these latter are dependent upon atoms of carbon, hydrogen and oxygen attached as side chains to the basic nucleus.

Aetioporphyrin is the porphyrin of chlorophyll. *Protoporphyrin* is the porphyrin of the blood pigment. It has probably the following constitution (see p. 41), and is an isomer of *oophorphyrin*—the brown pigment of the egg-shell.

(*Metallo-porphyrins*. Porphyrins are capable of forming compounds with various metals.) A pigment found in the feathers of a certain South African bird (turaco), for instance, and known as

Protoporphyrin (C₃₂H₃₂N₄(COOH)₂)

turacin, is a porphyrin combined with copper; Laidlaw has synthesized a pigment almost identical with turacin by uniting a porphyrin with this metal. Other metalloporphyrins have been prepared, namely, those of cobalt, nickel, silver, manganese, tin, zinc, etc.¹ Protoporphyrin combined with iron forms the metallo-porphyrin of the blood pigment. For instance, if an Fe atom be attached to protoporphyrin we get the iron-porphyrin compound of hemoglobin. This is called *heme* (C₃₄H₃₂N₄O₄Fe). As we shall presently see, however, heme is not peculiar to hemoglobin but is a constituent of other respiratory substances.

Heme is capable of combining with various proteins or nitrogenous substances, e.g., albumin, ammonia, pyridine, nicotine, etc. Such compounds are called *hemochromogens*. When globin is the protein with which heme is combined the resulting hemochromogen is that forming the basis of the blood pigment of vertebrate life. Hemoglobin is, therefore, an iron + porphyrin + globin compound.

THE HEMOCHROMOGEN OF HEMOGLOBIN. When hemoglobin is treated with alkali, its characters are changed. Its spectrum differs from that of hemoglobin. It still is capable of combining with oxygen, but unlike hemoglobin it does not readily release the gas again. For many years this modified hemoglobin, to which the term *hemochromogen* was first applied, was thought to contain only the pigment fraction (porphyrin + iron) of the hemoglobin molecule; the globin supposedly had been "sheared" off. The work of Anson and Mirsky however, has shown that this assumption is incorrect. No separation of globin from the pigment fraction occurs. Hemochromogen is a porphyrin +

iron + globin compound, just as is hemoglobin. The globin, however, has been denatured by the action of the reagents and to this denaturation the properties of hemochromogen whereby it differs from hemoglobin are ascribed. The iron is in the ferrous state (Fe⁺⁺). Hemochromogen consists therefore of denatured globin combined with the pigment complex C₃₄H₃₂N₄O₄Fe (heme).

When hemochromogen is exposed to oxygen a true oxide is formed. This is called *cathemoglobin*. The heme is oxidized—*oxidized heme*—the iron being in the ferric state (Fe⁺⁺⁺). Cathemoglobin is therefore oxidized heme (C₃₄H₃₂N₄O₄FeOH) united to de-natured globin.² *Methemoglobin* is oxidized heme combined with native globin.

It is evident, therefore, that when the globin is in its natural state, oxygen is taken up loosely by heme (oxygenation) but when denaturation of the globin occurs the true oxide of heme (oxidation) is formed.)

HEMIN (C₃₄H₃₂N₄O₄FeCl) is the hydrochloride of heme and is prepared by heating oxyhemoglobin with glacial acetic acid and a minimal amount of sodium chloride. Upon cooling, reddish brown prismatic crystals of hemin separate out. The detection of these, which are frequently referred to as Teichmann's crystals after their discoverer, is used as a test for blood in suspected stains. When hemin is treated with caustic soda oxidized heme is obtained. When the latter is treated with a weak acid the iron is split off and protoporphyrin remains. Hemin or blood itself when treated with concentrated mineral acids in the presence of oxygen yields hematoporphyrin (p. 46).

THE DISTRIBUTION OF HEME IN NATURE

(Heme is almost universally distributed throughout the animal and vegetable kingdoms. Respiratory pigments with this porphyrin-iron compound as their common basis are found in the lowest forms of plant life as well as in the highest species of animals.)

(CYTOCHROME is a heme compound which is widely distributed in the tissues of plants and animals.) It is present in certain aerobic bacteria, in yeast cells, in the onion, in worms, molluscs, crustacea, in the muscles of the bee's wing and in many other insects and their larvae. It is present in the muscles and other tissues of the large number of vertebrate species which have

¹ In chlorophyll the porphyrin is combined with magnesium.

² Oxidized heme is called *hematin* by some and heme is referred to as *reduced heme* by Anson and Mirsky.

been examined, from amphibia to mammals. Cytochrome plays an important part in the oxidation system in the tissues (p. 328). It undergoes alternate oxidation and reduction but unlike hemoglobin is not autoxidizable or only slightly so (due to component *b*, see below). In order to take up oxygen it requires the aid of tissue oxidase (indophenol oxidase); in order to undergo reduction it requires the presence of dehydrogenases. These activate the hydrogen of organic molecules in the tissue cells which become hydrogen donors. The cytochrome acts as a hydrogen acceptor. In this way cytochrome, it is suggested, serves as an intermediary in the transference of oxygen, liberated from hemoglobin, to the oxidizable materials in the tissue cells. It may also through component *b* serve for the direct transference of oxygen. In the presence of cyanides, carbon monoxide (in the dark) or sulphides which poison the oxidase, the oxidation of cytochrome is inhibited. On the other hand, anesthetics which depress the action of dehydrogenases prevent its reduction. In either case the link in the chain of oxygen usage by the cells is broken.

Cytochrome is a mixture of three hemochromogens; they are referred to by Keilin as *a*, *b* and *c*. Of these only *b* is autoxidizable. The heme components of the hemochromogens are not all the same, there being two varieties. One of these is identical with that in hemoglobin, the other resembles that in chlorocruorin, see below. The nitrogenous compounds with which the hemes are combined are unknown. Cytochrome is identified in living tissues by its characteristic absorption spectrum. The cytochrome of bees' wing muscle shows four absorption bands at 6046, 5665, 5501 and 5270 Angstrom units [see p. 44], respectively. Its oxidation and reduction can be followed in the living cell by means of the microspectroscope, the bands becoming distinct when reduction occurs but almost disappearing when the substance is oxidized.

Heme in the free state, that is, uncombined with a nitrogen compound has been discovered in many substances such as wheat flour and oatmeal where it had never been suspected. The fact that heme is in one way or another of such universal occurrence has prompted Barratt to remark, "man kind has for countless centuries been eating, all unknowingly, the outstanding constituent of his blood." It has been frequently suggested in the past that chlorophyll which also is constituted of pyrrol rings, was the primitive pigment and that animals probably derived the pyrrol grouping for the manufacture of the pigment of their bloods from this green coloring

matter in their diet. It is now seen, however, that heme is a much more ancient pigment; it is found in the most elemental forms of life in which chlorophyll does not exist. It is pointed out, however, on page 57 that the little evidence that either of these pigments in the diet serves as a basis for hemoglobin synthesis.

Hemoglobin itself is by no means so widely distributed as is heme and the heme component, cytochrome, for it is confined to the animal kingdom. It is found in the blood of all vertebrates and of several invertebrates, e.g., worm, certain snail, in the larvae of some but not in the body fluids of any adult insect. The blood components of different vertebrate species vary in their properties, the hemoglobin of the frog, for instance, possesses a different spectrum and oxygen dissociation curve from that of mammals. This variability is due to minor differences in globins to which the heme is joined and not to different hemes, which are the same throughout the vertebrate phylum.

Though many different porphyrins exist, only differing from protoporphyrin has been discovered in nature as forming part of a hemoglobin-like substance, i.e., one in which the nitrogenous fraction is probably a globin. A hemoglobin-like pigment, greenish color, is found in certain worms and is called *chlorocruorin*. It contains this other porphyrin of unknown structure combined with iron. *Helicorubin* is a respiratory pigment found in the gut and liver of snail. It contains the same heme as hemoglobin, as shown by the fact that if its non-pigmented fraction be replaced by pyridine the pyridine-hemochromogen so formed shows a spectrum identical with that of pyridine-hemochromogen derived from hemoglobin. *Chlorocruorin*, however, since its heme is different when treated similarly shows a different spectrum. The nitrogenous part of *helicorubin* is unknown, presumably it is not globin.

Hemerythrin is a respiratory pigment which occurs in certain crustacea and molluscs (king crab, octopus, snail) takes the place of hemoglobin. It is dissolved in the circulating fluid and not confined within cells. This substance contains copper instead of iron; the metal is not combined with a porphyrin as is believed at one time. This pigment is blue when oxidized and colorless when reduced.

SUMMARY

Some of the points in the preceding paragraphs may be summed up in the following scheme:

(Pyrrol nucleus)₄ = a porphyrin compound
 Porphyrins + metals = metallo-porphyrins, hemes

Protoporphyrin + iron (Fe^{++}) = heme

Heme + various nitrogenous substances = hemochromogens of various respiratory pigments, e.g., cytochrome, helioerythrin, etc.

Heme (iron in ferrous state) + globin = hemoglobin (see also scheme on p. 45)

Heme + denatured globin = hemochromogen of hemoglobin

Oxidized heme (iron in ferric state) + denatured globin = cathemoglobin

Oxidized heme + globin = methemoglobin (p. 44)

THE MOLECULAR WEIGHT OF HEMOGLOBIN

The pigment proper (heme) constitutes about per cent and the globin about 96 per cent of the hemoglobin molecule. The small but relatively heavy porphyrin-iron portion is floated, as it were, by the large protein fraction. If hemoglobin contained only 1 atom of iron which has a molecular weight of 56, then since the percentage of the metal in hemoglobin is 0.336, as determined by direct analyses, the minimum molecular weight of hemoglobin would be $\frac{56}{0.336} \times 100 = 16,700$, approximately. Hufner obtained in fact a figure of 16,800 from osmotic pressure measurements.

Adair, however, from a study of the osmotic pressure of hemoglobin finds the molecular weight to be approximately four times greater, namely, 68,000. The molecule contains 4 atoms of iron. Using an entirely different but most ingenious physical method, namely, ultracentrifugation, Svedberg obtained a value almost identical with Adair's. Solutions of hemoglobin were centrifuged at great speeds for several hours so as to force the sedimentation of the hemoglobin molecule, which under ordinary circumstances of course, does not separate from solution. When a solution is subjected to a centrifugal force 200,000 times that of gravity, a conflict between two opposing forces occurs. Centrifugal force tends to throw the particles down out of the solution, diffusion, on the other hand, tends to prevent their sedimentation. The rate of sedimentation will therefore be a measure of the degree to which the centrifugal force overbalances the rate of diffusion. The rate of diffusion but not that of sedimentation depends upon the molecular weight. So it is possible to calculate the molecular weight indirectly from an equation based upon the sedimentation value but also including a number of other factors.

Northrop and Anson also obtained a figure of around 68,000 from calculations based upon the rate of diffusion of hemoglobin through discs of alundum. Hemochromogen is probably a depolymerized form of hemoglobin with a molecular weight of 16,700, or double this value.

Human blood contains about 15 grams (14 to 16 grams) of hemoglobin per 100 cc. Since the proportion of iron in hemoglobin is 0.336 per cent, the quantity of the metal in 100 cc. of blood is about 50 mg. and in the total blood of the human body about 4 grams. The total quantity of hemoglobin of an average sized man is about 1 kg. or about 14 grams per kilogram of body weight. The blood contains a small proportion of iron in addition to that combined with hemoglobin (p. 58).

THE ESTIMATION OF HEMOGLOBIN IN BLOOD. A determination of its oxygen capacity is the most accurate means of obtaining the hemoglobin concentration of a sample of blood (p. 318). A number of clinical methods are available for estimating the hemoglobin concentration as a percentage of the normal. Only one, namely that of Gowers as modified by Sahli and by Haskins, will be described. Dilute HCl (0.2 N) is placed in a small graduated glass tube up to the mark 10. 0.02 cc. of the blood under examination is delivered into the acid with a Sahli pipette which is rinsed by drawing the acid blood mixture into it twice and blowing out each time. The tube is kept at a temperature of about 60°C. for 7 minutes. When the full reddish brown color of the acid hematin (hemin) which is formed has fully developed, the tube is placed in a comparator alongside a standard color solution and carefully diluted with water until the two colors exactly match. The hemoglobin percentage is given by the figure on the tube at the level of the mixture. The temperature of the standard should be kept at around 20°C. while the color comparison is being made. Blood containing 13 grams of hemoglobin per 100 cc. gives a reading of 100 per cent. The blood of the average healthy person would therefore give a reading of 110 per cent.

Myoglobin or muscle hemoglobin, the pigment of muscle, resembles blood hemoglobin in its function. It acts as an oxygen reservoir within the muscle fiber which serves to tide the muscle over from one contraction to the next. It has a higher oxygen affinity than has blood hemoglobin and can combine with oxygen and dissociate from it with great rapidity (less than 1/100 second). Myoglobin starts to give up its oxygen at the instant that the muscle contracts. Its oxygen store is replenished during the resting state.

COMBINATIONS OF HEMOGLOBIN WITH GASES

Oxygen (see also chapter XXXII)

Hemoglobin combines with oxygen by virtue of the iron which it contains. The two elements combine according to the law of definite propor-

tions, two atoms of oxygen uniting with each atom of iron in the hemoglobin complex. Thus

The combination of oxygen with hemoglobin is a most unstable one. When the oxygen pressure of the atmosphere in contact with hemoglobin is raised, oxygen is taken up but no true oxide is formed. The iron remains in the ferrous state. It is the globin which endows the iron-pigment part of hemoglobin with the unique property of forming a loose combination with oxygen: the latter is lost once denaturation of the protein occurs. Hemoglobin *oxygenated* (not *oxidized*) in this way is known as *oxyhemoglobin*. The term *reduced hemoglobin* implies that the pigment has given up a part of its oxygen store.

The capacity of the blood for absorbing oxygen—the *oxygen capacity* as it is called is proportional to the hemoglobin concentration. The oxygen capacity of a gram of hemoglobin is 1.34cc. So the oxygen capacity of 100 cc. of normal human blood (15 grams Hb) is ($15 \times 1.34 =$) 20 cc. The union of oxygen with hemoglobin will be dealt with more fully in the section on respiration.

METHEMOGLOBIN. This is a true oxide. One atom of oxygen combines with one of iron, and the gas cannot be removed by exposing the blood to a vacuum; it can be removed only by chemical reagents. Methoglobin is, therefore, a compound of oxidized heme (i.e., heme containing ferric iron) with native globin and thus differs chemically from cathemoglobin which is ferric heme plus de-natured globin. When potassium ferricyanide is added to oxyhemoglobin, as in the Haldane method of determining the oxygen content of a sample of blood (p. 318), the two loosely bound atoms of oxygen are easily displaced but the iron is oxidized by the reagent and methemoglobin formed.¹ In poisoning by certain drugs, e.g., nitrites, chlorates, sulphates, acetanilid, bismuth subnitrate, nitrobenzine compounds, sulphanilamide, etc., the blood becomes dark in color due to the formation of methemoglobin and gives rise to a type of cyanosis (p. 373) to which the

¹ The change is explained in the following way. The ferricyanide oxidizes the reduced hemoglobin which is in equilibrium with the oxyhemoglobin

The equilibrium is re-established by the passage of oxyhemoglobin into the reduced state, i.e., the oxyhemoglobin gives up its oxygen with the result that a loose compound of oxygen with hemoglobin is replaced by a true oxide of hemoglobin, i.e., methemoglobin

term "toxic" is applied.⁴ The discoloration of the skin becomes evident when the methemoglobin amounts to about 3 grams per 100 cc. of blood. Methylene blue when injected into the blood stream causes the formation of methemoglobin. The employment of this dye in the treatment of cyanide poisoning is dealt with on page 373.

Sulphemoglobin

Reduced hemoglobin combines with hydrogen sulphide to form sulphemoglobin which gives blood a chocolate color. Except perhaps extreme cases of intestinal putrefaction hydrogen sulphide is not absorbed in appreciable amount. But it appears that certain drugs notably acetanilid

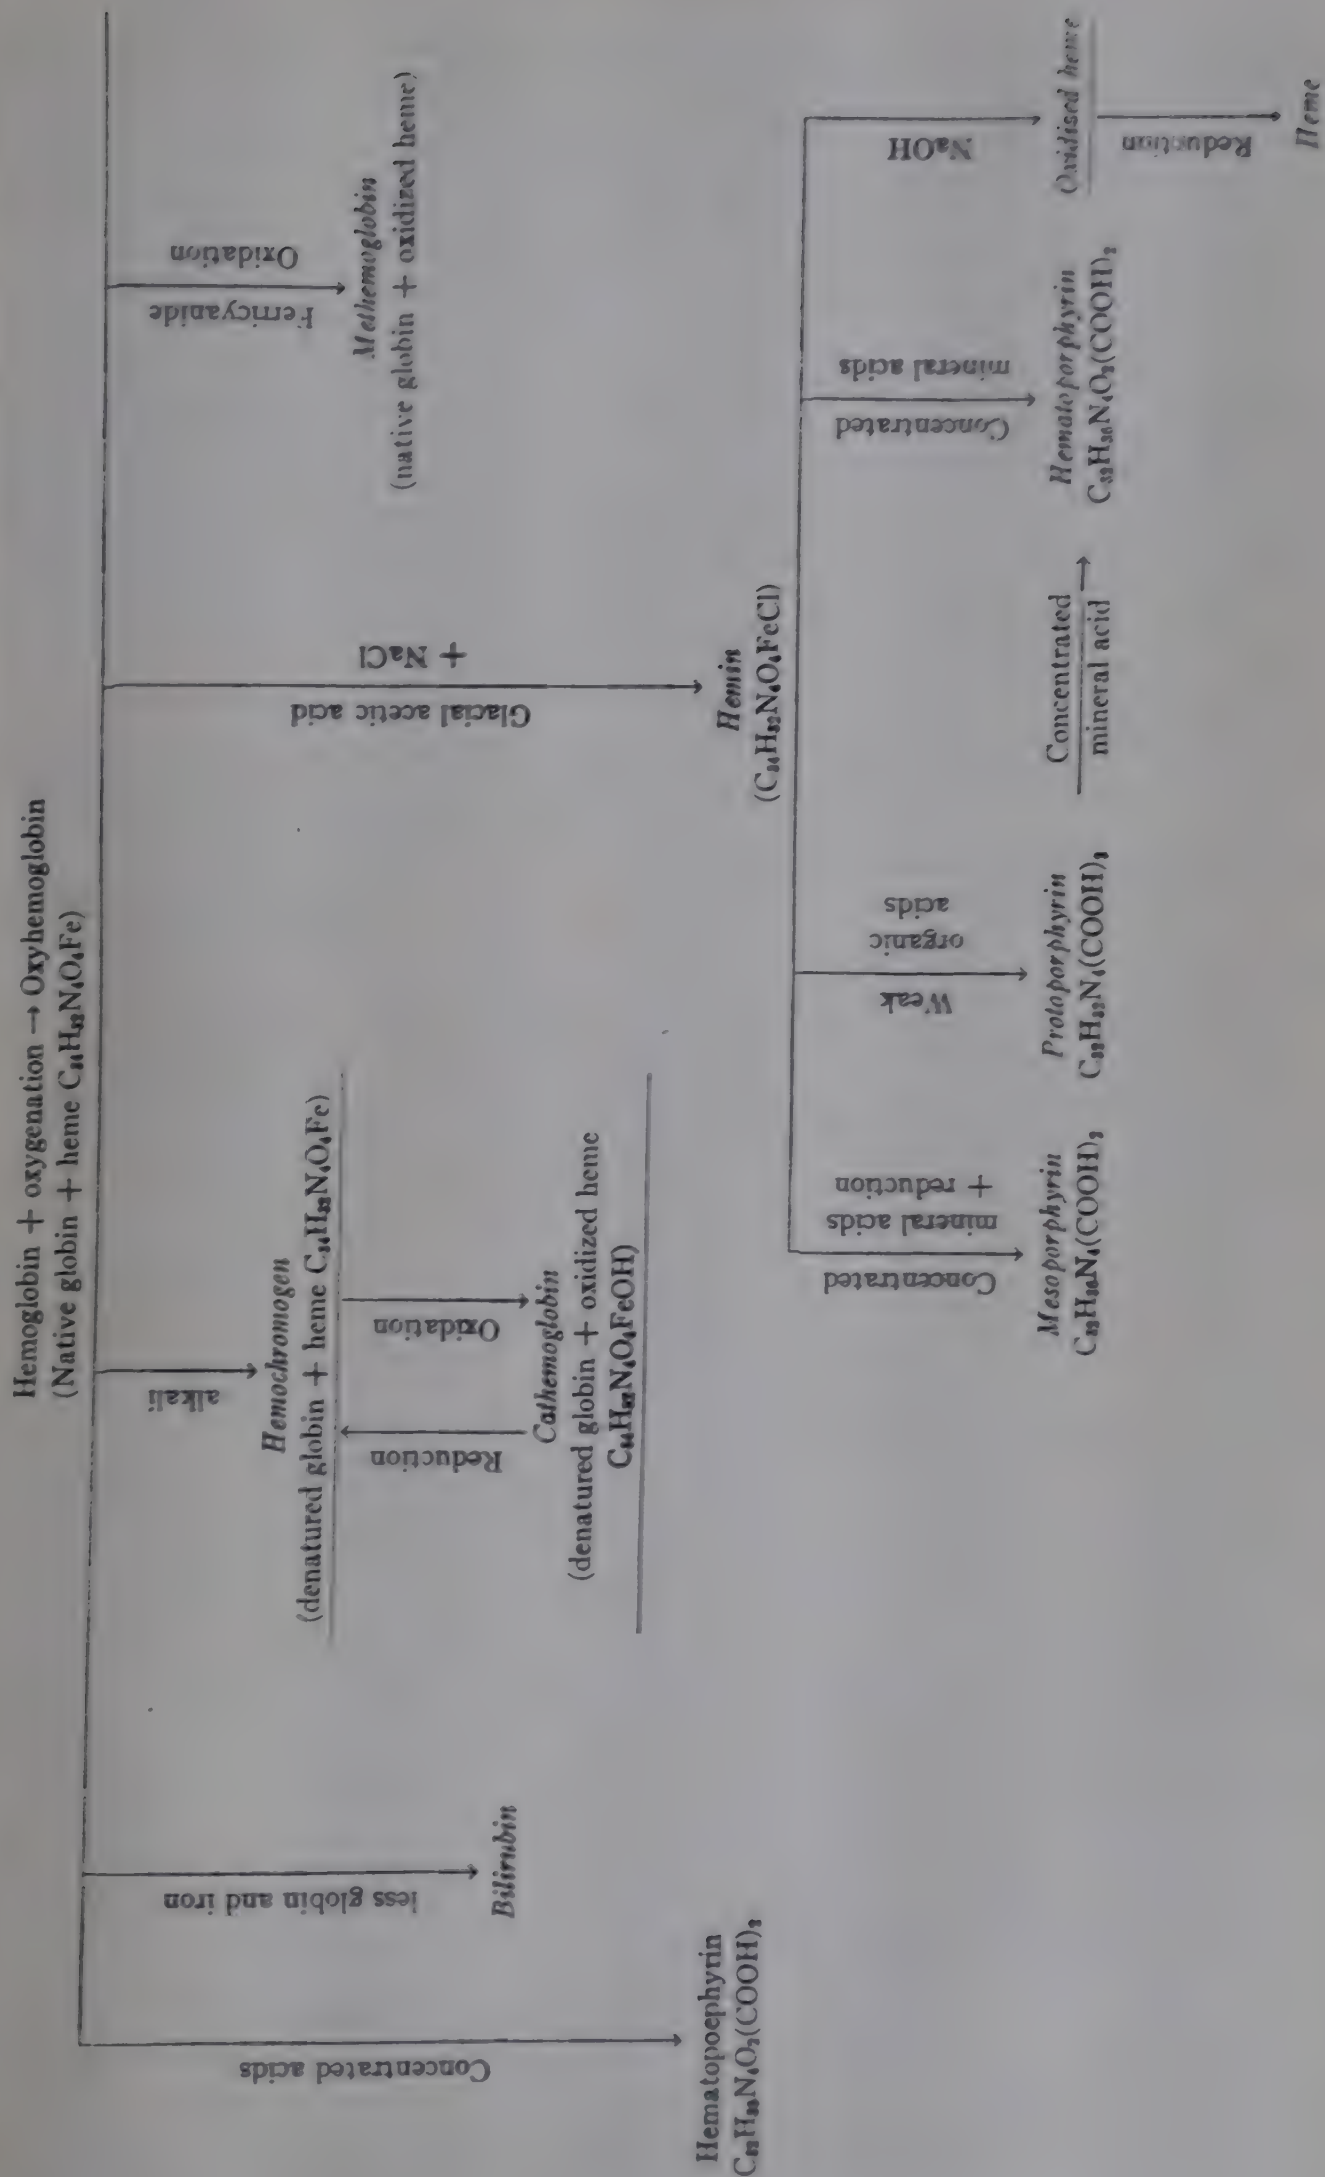

FIG. 14. Absorption spectra of hemoglobin and some of its derivatives (after Peterson, Haines and Webster, *Legal Medicine and Toxicology*).

(which is contained in bromo-seltzer) and phenacetin sensitize hemoglobin so that it combines more readily with hydrogen sulphide. Small quantities of the gas absorbed from the alimentary canal may then cause sulphemoglobin to reach a relatively high concentration in the circulation and give a bluish or mauve tint to the skin. This so-called *enterogenous cyanosis* occurs when an abnormal compound amounts to from 3 to 5 grams per 100 cc. of blood. The presence in the blood of sulphemoglobin or of methemoglobin is detected by spectroscopic examination (fig. 14).

⁴ According to Meulengracht and his associates the cyanosis caused by acetanilid is due to the decomposition of the drug to dark colored derivative para-amido-phenol rather than to the formation of methemoglobin.

Carbonyl-hemoglobin and nitric oxide hemoglobin

Carbon monoxide combines with hemoglobin in the same proportion as does oxygen. It competes successfully with the latter for hemoglobin and displaces it volume for volume to form carboxyhemoglobin. Unlike oxygen, however, it forms with hemoglobin a stable compound which can be disrupted only with the greatest difficulty. The much greater avidity (between 200 and 250 times) which hemoglobin shows for CO renders the gas so highly dangerous when inhaled in any considerable quantity (see p. 371). **Nitric oxide** gas also has a strong affinity for hemoglobin and forms a stable compound with it. The fumes given off by high explosives during their combustion contain large amounts of nitric oxide and the commonest way in which this poisoning occurs is through persons entering a closed space after an explosion, before the gas has cleared away.

Pigment complexes derived from hemoglobin but free from iron and globin

Hematoporphyrin, $C_{54}H_{54}O_8N_4(COOH)_8$, is an artificial derivative obtained by the action of strong mineral acids upon hemoglobin or upon hemein. It is closely related to protoporphyrin—the natural porphyrin of hemoglobin but contains two more molecules of water. By reduction hematoporphyrin is converted to **mesoporphyrin** $C_{54}H_{54}N_4(COOH)_8$.

Coproporphyrin, $C_{52}H_{52}N_4(COOH)_8$, formed in the intestine from bilirubin is found normally in human feces, and in urine, bile and milk in traces.

Uroporphyrin, $C_{54}H_{54}N_4(COOH)_8$, is present in minute amounts in normal urine. The copper salt of this porphyrin is **turacin** mentioned on page 41. Coproporphyrin and uroporphyrin are produced in excessive quantities in the condition known as **hematoporphyrin**. Neither of them, however, is derived in the body from the breakdown of hemoglobin. Under normal circumstances they are largely derived from the porphyrins of plant and animal tissues taken as food. Their excretion is therefore moderately increased by a diet of high porphyrin content, e.g., meat and certain vegetables. Hematoporphyrin and uroporphyrin when injected into animals causes them to become highly sensitive to the rays of visible light. If given a large injection and then placed in a bright light, urgent symptoms quickly appear and death results. If the animal is kept in the dark no ill effects result. If smaller doses of the porphyrin are given over a period erythema, eczema and other skin lesions develop.

Bilirubin, $C_{43}H_{56}N_4O_6$ (p. 433) contains the four pyrral groups but the arrangement of these has been changed so that they no longer form the ring structure typical of a porphyrin. By oxidation of bilirubin in

its passage through the liver biliverdin, $C_{43}H_{56}N_4O_6$, is formed. Bilirubin is converted by reduction in the intestine to stercobilinogen, also called urobilinogen (p. 410). Urobilin, is formed by the oxidation of stercobilinogen, and is present in very small quantities in normal urine, but is not the pigment responsible for the color of urine (p. 398).

Absorption spectra. The various heme pigments and the compounds of hemoglobin when placed in the path of a beam of white light absorb waves of certain lengths but transmit the rest. That is, each possesses a characteristic absorption spectrum and it is by means of spectroscopy that they may be most readily detected. The different hemochromogens, reduced hemoglobin and oxyhemoglobin, CO and NO hemoglobin, hematoporphyrin, coproporphyrin, cytochrome, urobilin, etc. have all their specific absorption bands. See table 8.

TABLE 8

Wave lengths (λ) at the points of maximum intensity of absorption bands of hemoglobin and its derivatives as well as some of the other heme compounds

COMPOUND	NUMBER OF BANDS	SITUATIONS OF ABSORPTION BANDS WAVE LENGTHS IN ANGSTROM UNITS

Urobilin	1	4900	—	—	—

Hematoporphyrin. This is a condition due to disordered porphyrin metabolism. Large quantities of uroporphyrin and coproporphyrin are excreted, the former giving a port wine color to the urine. The bones and teeth may be stained brown or pink by the pigment. It is unfortunate that the disease has been called hematoporphyrin for as just mentioned the porphyrins produced in excess are uroporphyrin and coproporphyrin and not hematoporphyrin which is an artificial substance resulting from the action of laboratory reagents. The condition is frequently congenital and runs a chronic course but it may be acute and arise from no known cause or may follow the prolonged use of such drugs as sulfonal or trional and possibly veronal. The disease has a high mortality. During life, symptoms referable to the gastrointestinal tract and nervous system, e.g., abdominal pain, nausea, vomiting and an ascending paralysis, are prominent. In the chronic cases sensitivity to light rays is evidenced by skin eruptions, e.g., erythema, vesic-

bullae, and the port wine color of the urine are the features. In hematoporphyria the porphyrins are not believed to be derived from the breakdown of hemoglobin. Coproporphyrin or uroporphyrin can be obtained from hemoglobin by laboratory means, without disrupting the pyrrol grouping and it is unlikely that the body can effect the transformation. There is, as a rule, no evidence of any abnormal destruction of red cells and in animals destruction of red cells induced by various means does not increase the output of porphyrins. It is thought rather that the disease is due to overproduction of these porphyrins at a certain stage in hemoglobin synthesis—a reversion to an embryonic type of pigment metabolism. The red cells of the embryo contain uroporphyrin as well as hemoglobin. Porphyrin is also present in the primitive

cells found in certain anemias. Hemoglobin is a more highly specialized type of the more generally distributed and more primitive respiratory pigments. It is not improbable that such heme pigments serve purposes in the early embryonic life of mammals which are served in later embryonic life and in the adult by the more highly specialized hemoglobin. At a certain stage in development hemoglobin production from these pigments would commence. Primitive pigments and hemoglobin would thus be formed at the same time. In hematoporphyria it is suggested that the primitive type of pigment formation persists.

Though there is no evidence, it is possible that the porphyrins in this disease are derived from myoglobin, cytochrome or other porphyrin compounds of the tissues.

CHAPTER VII

HEMOLYSIS AND SUSPENSION STABILITY OF THE BLOOD

HEMOLYSIS OR THE LAKING OF BLOOD

Under normal circumstances the plasma contains no appreciable quantity of hemoglobin. If normal blood be centrifuged the corpuscles are driven to the bottom of the tube while the supernatant plasma is clear but faintly straw-colored. Under certain conditions, however, changes may occur in the red cell which will allow the hemoglobin to escape into the surrounding fluid, which then becomes discolored. This² is called *hemolysis* or *laking*, and may be carried out in a test tube by means of various agencies both physical and chemical. Certain biological substances, such as the toxins of bacteria, snake venoms, are intensely hemolytic. On the other hand, substances belonging to the class of immune substances or antibodies, and known specifically as hemolysins, are formed in the blood. These have the power to hemolyse foreign red cells. After the action of certain hemolytic agents the dim colorless outline of the red cells—shadow cells or “ghosts”—may be seen; they represent the incompletely destroyed framework of stroma.¹ (See frontispiece.) Some of the means by which hemolysis may be induced may now be considered in greater detail.

(1) Hypotonic solutions

The membranes of plant and animal cells are semipermeable (p. 23). They allow the passage into the cell of water and various substances in solution, but offer a barrier to the entrance or egress of others. The red cell is no exception; it contains substances (p. 339) which cannot pass out, and is surrounded by a fluid (plasma) containing materials which cannot pass in. We have here then a minute and almost perfect osmometer (p. 23), and indeed much of our knowledge of osmotic phenomena has been gained from the study of the behavior of plant and animal cells when placed in solutions of different concentrations. In normal blood the plasma and the corpuscles are in osmotic equilibrium, i.e., the fluids separated by

the corpuscular membrane are isotonic. If, however, the dissolved substances in the plasma be diluted by the addition of distilled water, a flow of water into the corpuscles occurs. An osmotic pressure is developed within it which the cell membrane is unable to withstand. The cell swells and becomes globular, the membrane stretches and finally bursts, liberating its hemoglobin.

The process is in reality rather more complicated than this. It is probable that the hemoglobin is not contained within the red cell merely as in a bladder, or even in a number of smaller compartments, but is bound in some way to the cell structure.³ One reason for this belief is that purely mechanical agencies will not liberate the pigment. The cell may be torn into the finest shreds, yet each minute particle still retains its hold upon the hemoglobin. The pigment, however, is soon released when the surrounding fluid is made hypotonic. This suggests that the cell structure consists of semipermeable partitions of almost infinite fineness.

The normal red cell offers a certain resistance to the disintegrating effect of hypotonic solutions. A slight lowering of the osmotic pressure of the surrounding fluid will not produce hemolysis. The normal percentage of salts in human plasma is approximately 0.94. Normal cells may be placed in a 0.6 per cent saline solution without being hemolyzed. The cell increases in volume, but the membrane remains intact. Hemolysis commences when the saline concentration is reduced to about 0.40 per cent and is complete at 0.34 per cent. The resistance which erythrocytes offer to the hemolytic action of hypotonic solutions is used in this way as an index of the fragility of the red cells. In pernicious anemia the red cells have been found to be actually less fragile than normal whereas in other conditions, e.g., some forms of purpura (p. 94) and chronic hemolytic jaundice, their fragility is increased.

The permeability of the membrane of the red cell is therefore quite different from that of the capillary membrane which as we have seen (p. 42) allows the passage of all crystalloid substances and

¹ When hemolysis is induced by certain reagents, e.g., linoleic acid, but the cell structure remains intact, the addition of electrolytes causes the reappearance of hemoglobin in the cells (“reversed hemolysis”). This phenomenon is due probably to shrinkage of the cells and the concentration of unliberated pigment and not to the return of hemoglobin to the cell.

³ According to Schafer the red cell is simply a drop of colored fluid enclosed by a membrane, but it is difficult to explain the very definite shape of the cell without presuming that it possesses a stroma of some sort.

to some extent of plasma protein; it is also freely permeable to hemoglobin. The membrane of the erythrocyte, on the other hand, is impermeable to hemoglobin and the plasma proteins and to the cations Ca^{++} , K^{+} , Mg^{+} and H^{+} , but permits the passage of water and the anions Cl^{-} , HCO_3^{-} , OH^{-} and PO_4^{-} . It appears that, contrary to previous belief, the erythrocyte is permeable to sodium. Since the cell is impermeable to the smaller K ion, its selective permeability cannot be explained simply upon the theory that the cell membrane is a sieve-like structure whose "pores" are of such a size as to allow the smaller ions, but not the larger ones, to pass. The lipid-soluble theory is also unsatisfactory, for the inorganic anions are lipid-insoluble. The cell membrane is freely permeable to amino acids, urea and uric acid, so these substances under ordinary circumstances do not enter into the osmotic relationships between cells and plasma. Osmotic changes occur, however, when CO_2 enters the blood and diffuses into the cell (see p. 337).

(2) Chemical substances

Ether, chloroform benzene and alcohol act by dissolving the lipid constituents of the envelope and stroma of the cell. Other substances, e.g. *bile salts, acids and alkalis* and *saponin* cause hemolysis, but the manner in which they act is not altogether clear. Bile salts probably act by combining with the protein constituents, and saponin with the cholesterol. As a result of the chemical changes induced by either of these substances, destruction of the cell stroma—*stromatolysis*—occurs. Acids probably act by penetrating the cell and increasing the osmotic concentration within. Swelling and liberation of the hemoglobin occurs in a manner analogous to that of hypotonic solutions. The stroma is not as a rule destroyed. Alkalis, particularly ammonia, are powerfully hemolytic, as is also ammonium chloride. The NH_3 enters the cell and through the increase in osmotic pressure causes swelling and liberation of the hemoglobin. Stromatolysis occurs following the hemolysis by alkali.

Certain chemical poisons such as carbolic acid, nitrobenzene, pyrogallol, ricin, arsenical preparations used in the treatment of syphilis, and many other substances are capable of causing red cell destruction.

(3) Substances of bacterial origin or formed in the animal body

(a) SPECIFIC HEMOLYSINS. If blood be injected into the veins of an animal of another species, or as already mentioned (p. 35) into an individual of the same species but whose blood group is incompatible with the blood group to which the injected blood belongs, agglutination of the red cells of the donor occurs, and hemolysis fol-

lows as a secondary effect. But if a series of injections of erythrocytes be injected over a period of days into the blood of another species the serum of the latter develops a substance which promptly destroys the foreign cells through a *primary* hemolytic effect quite independent of agglutination. This hemolytic reaction, which was first demonstrated by Bordet, is specific, that is to say, it is only the particular species of erythrocyte to which the animal has been sensitized by previous injections that is destroyed by the hemolytic substance. The latter on this account is known as a *specific hemolysin*. It belongs to the class of immune substances or antibodies. Bodies of similar nature cause the destruction of other foreign cells and are known as cytolytins and bacteriolysins. All are part of a general protective mechanism which the body is able to build up against the invasion of foreign cells. When referring to these and other immune reactions the substance which upon entering the body causes their development is referred to as the *antigen* (i.e., the foreign red cells in the case of hemolysins). The antibody itself (e.g., the hemolysin) is heat stable and is spoken of as the *amboceptor*. The latter which is specific requires for its action another body which is nonspecific, is present in all sera and is destroyed by heat. It is known as the *complement*. Three factors (antigen, amboceptor and complement) are therefore necessary for the hemolytic or bacteriolytic reaction. After the action of the hemolytic or bacteriolytic amboceptor has been annulled through destruction of the complement by heat, the reaction may be restored by the addition of any serum (i.e., by supplying fresh complement).

When serum which has developed a bacterial antibody is incubated with an emulsion of the particular bacteria which has served as antigen, a reaction occurs which "fixes" or binds the complement. The phenomenon is spoken of as *complement fixation*. These facts were applied by Wassermann to the diagnosis of syphilis, and by subsequent workers as a test for other diseases, e.g., tuberculosis. For example, the previously heated serum of a subject suspected to be suffering from syphilitis, is incubated with (a) an emulsion of syphilitic liver¹ tubercle or typhoid bacilli respectively (the antigen) together with (b) complement furnished by normal guinea-pig's serum. If the suspected serum contains a specific antibody (amboceptor) for the antigen employed, the former will bind the complement to the latter, i.e., fixation of complement will occur. The foregoing is an account of a bacteriolytic system. An hemolytic system is employed to render the reaction visible. Washed sheep's corpuscles are added to the former system, together with the previously heated serum of a rabbit which has been sensitized to the latter cells by repeated injections. This serum supplies the hemolytic amboceptor but its complement has been

¹ As a matter of fact syphilitic liver has been found to be unnecessary, since lecithin and other materials for some unexplained reason will serve as antigens.

destroyed. If the test is positive no hemolysis of the corpuscles occurs, since the complement (non-specific) of the patient's serum has been already fixed by the bacteriolytic amboceptor and the hemolysin of the rabbit serum is therefore unable to exert its usual effect.

(b) **TOXIC SUBSTANCES OF BACTERIAL OR PARASITIC ORIGIN.** *Endogenous* poisons of unknown origin. The toxins of bacteria responsible for many diseases, e.g. streptococcus, staphylococcus, tetanus bacillus and the organism of scarlet fever or the malarial parasite may cause a destruction of red cells. The more virulent types of other infectious fevers, e.g., smallpox, diphtheria, are also sometimes accompanied by intense hemolysis. When the hemolysis is of moderate degree but occurs over longer periods the hemoglobin is converted into bile-pigment. This, if formed in amounts greater than can be disposed of by the liver, undergoes partial retention in the plasma, which together with the solid tissues, especially of the skin and mucous membranes, becomes stained a yellowish tint—hemolytic jaundice (p. 463). In hemolytic states of long standing an iron containing derivative of hemoglobin termed *hemosiderin* is frequently deposited in large amounts in the tissues, particularly of the liver and spleen (p. 60).

When the hemolysis reaches such a degree that the hemoglobin cannot be converted into bilirubin as rapidly as it is liberated, as in severe malaria (black-water fever) *hemoglobinuria* occurs, that is, the pigment is passed in the urine, which is usually turned a dark brown or even black color, due to the action of the urinary acid in converting the pigment into methemoglobin. The concentration of hemoglobin must, as a rule, reach a level of about 0.7 gram per 100 cc. of blood before it appears in the urine. It should be remembered that hemoglobin once it has escaped from the erythrocytes is functionless. Not only is it unable to be retained within the capillaries on account of the relatively small size of its molecule but the environment of the plasma is unsuitable for its action. An endogenous poison of some sort is probably responsible for the hemolysis that occurs in the condition known as *paroxysmal hemoglobinuria*. An attack of this disease is precipitated most usually by chilling of the body surface, but may follow emotional disturbances or undue muscular exertion. The condition is sometimes associated with Raynaud's disease, in which condition spasmodic constrictions of the small vessels of the peripheral parts of the body occur, particularly after exposure to cold. The occasional association of the two conditions has suggested to some that they have a common cause. Direct evidence for this, however, is wanting. It is an interesting and suggestive observation that though the cells of normal blood are unaffected by cold, the blood of a subject of paroxysmal hemoglobinuria if cooled (to 5°C.) outside the body and subsequently warmed undergoes hemolysis (Donath phenomenon). There is apparently no defect, however, of the subject's corpuscles; they seem to be no less resistant than normal to hypotonic saline; the serum,

on the other hand, has the power to hemolyze the cells of a normal person. The great majority of subjects give a positive Wassermann reaction.

March hemoglobinuria. Hemolysis may occur and hemoglobin appear in the urine even in healthy persons after strenuous muscular effort. In certain persons this tendency is exaggerated and hemoglobinuria may follow relatively mild muscular exercise. It is seen not infrequently in soldiers after long marches. The free pigment in the blood and urine of such cases is erythromyoglobin, not myoglobin as might be expected. The fragility of the red cells is not increased and no hemolysins nor autoagglutinins which might account for the hemolysis have been discovered.

In a third type of paroxysmal hemoglobinuria—the *nocturnal hemoglobinuria of Marchiafava*—hemoglobin or hemosiderin (p. 60) is passed almost continuously in the urine, but in greatest amounts at night. It is accompanied by a severe hemolytic anemia.

(c) *The Venoms of Certain Poisonous Snakes*, e.g. the cobra, and the poisons of various stinging insects and spiders cause a destruction to a greater or less degree of the red cells. Snake venom (cobra) has been shown to act indirectly. It contains a principle which has power to remove unsaturated fatty acids from the lecithin molecule. The resulting product which is called *lysolecithin*, is intensely hemolytic. Since lecithin is present both in erythrocytes and plasma and indeed in all cells, the entrance of snake venom into the body causes the production of this intensely hemolytic substance. Cephalin is acted upon by snake venom in a similar manner with the production of *lysocephalin* which has a similar hemolytic action.

THE SUSPENSION STABILITY OF THE BLOOD

The blood is a suspension of cells in a viscous fluid, the plasma. It is only the constant movement of the fluid that keeps the cells evenly distributed throughout. When the circulation comes to rest the cells at once commence to sink. Under ordinary circumstances the sedimentation of the cells, even in the blood withdrawn from the body, can progress to only a negligible extent, for it is soon circumvented by the clotting process which fixes them in a jelly-like matrix. If for any reason the blood is delayed from clotting, sedimentation may continue until an upper layer of clear plasma becomes separated from the cells which have descended through the fluid. When clotting then ensues the blood consists of two strata, a thin yellowish or buff-colored layer of clotted plasma laid upon a much deeper red stratum of cells. When blood had clotted in this way the upper layer was known to the older physiologists as the "buffy coat" (see also p. 88), while the ancient

thought it was the "phlegm" of the blood which had undergone separation from the other humors.

It has been shown by Fahraeus that the rate of sinking—the *sedimentation rate*—of the red cells varies in disease and under certain conditions of health. The rate is measured by the depth in millimeters of clear plasma which is formed at the top of a vertical column of blood by the end of one hour. The blood for examination is diluted 4 parts to 1 of a 3 per cent solution of sodium citrate. It is then drawn into a glass tube, with a bore of 2.5 mm. to a height of 60 mm.⁴ The upper end of the tube which is fixed in a strictly perpendicular position is left open, while the lower end is closed by a rubber cap held in position by a spring. The sedimentation rates of clear plasma

FIG. 15. Showing the naked-eye appearances of specimens of blood spread upon glass slides. The specimens, left to right, are from, *a.* healthy man (2), *b.* healthy woman (7), *c.* healthy pregnant woman (28), *d.* man, appendicitis (40), *e.* man, pneumonia (68), *f.* sepsis (102). Note granular appearance of specimens *d.*, *e.*, and *f.* Figures in brackets indicate sedimentation rates, mm. per hour (after Fahraeus).

per hour were found for different normal bloods to be as follows:

	mm. per hour
Men.....	1-3
Women.....	4-7
Newborn children.....	0.5

These figures for the sedimentation rate are an index of what is termed the suspension stability of the blood. In normal pregnancy and in certain pathological states, the sinking rate of the red cells is found to be very markedly increased; in other

⁴In some methods the blood is drawn to a higher level than this, but according to Walton the most consistent results are obtained with a column of blood of this height. Since the concentration of the blood in red cells influences the sinking rate, it is also recommended that their number be standardized to 5,000,000 cu. mm. by the addition or removal of plasma if the subject's blood is below or above this level.

words, the suspension stability of the blood is reduced. The average figure during pregnancy is about 35 mm. per hour. The rate is also increased during menstruation. The pathological states which show the most noteworthy increase in the rate are septicemia, 100 mm. per hour, and pulmonary tuberculosis, 65 mm. Anemia, malignant tumors, inflammatory conditions of the female pelvic organs and many other conditions moderately increase the rate above the normal. *Reduction* in the sedimentation rate is rare; it occurs in allergic states, in peptone shock and in sickle-cell and hemolytic anemias.

The physical changes in the blood which might cause this unusually rapid rate of red cell settling are of considerable interest and were investigated thoroughly by Fahraeus. In considering the sedimentation rate of particles suspended in a fluid when they are of a size comparable with that of the red cells, four factors must be taken into account. These as applied to blood are:

(1) *Specific gravity* of the plasma as compared with that of the corpuscles. Corpuscles of high specific gravity would sink more quickly in normal plasma, and normal corpuscles would settle more quickly in a plasma with a low specific gravity. In neither corpuscles nor plasma was any significant change of this nature discovered.

(2) *Lowered viscosity* of the plasma is another factor which could cause an increase in rate of sinking, but no such change could be detected.

(3) *Increased size of the corpuscles* would increase their mass disproportionately to their surface and in consequence enhance their rate of sinking, but no significant alteration in size was found.

(4) *Clumping* together of cells of normal size would have the same effect as an increase in size of the individual cells for just as lumps of clay sink rapidly in water, while clay in the form of fine particles remain suspended almost indefinitely, so aggregation of the corpuscles would cause their more rapid sedimentation.

This last factor was found to be the cause of the lowered stability of the blood suspension in the pathological conditions cited above. The roughness and granular appearance of the blood, due to the corpuscular aggregation is evident to the naked eye when the blood is spread in a film upon a slide (fig. 15). Normal blood, in marked contrast, forms a smooth homogeneous film. Under the microscope the crowding together of the cells in large masses is quite obvious. An increase in the fibrinogen and globulin fractions of the plasma is held responsible for the effect. These proteins act upon the corpuscles in some unknown way to make

them adhere to one another and form clumps of agglutinated cells⁶ (auto-agglutination). That the character of the plasma and not that of the cells is the determining factor is shown by the fact that if erythrocytes from blood with a high sedimentation rate (e.g., of pregnancy) are suspended in the plasma of blood having a low rate of sedimentation (e.g., of newborn) they settle at the slower rate.

⁶ The red cells of normal blood show an incipient tendency to cling together in chains—the so-called *rouleaux* formation.

The non-specificity of the test is evident; nevertheless determinations of the sedimentation rate are of considerable value (1) in gauging the degree of activity of tuberculous processes; (2) as an aid in the differential diagnosis of certain gynecological lesions. Benign tumors of the pelvic organs cause no change in rate whereas, as already mentioned, malignant growths, inflammatory states and pregnancy cause a pronounced rise; (3) as an index of the extent and intensity in pyogenic infections and (4) in estimating the activity of the inflammatory process in rheumatic fever.

CHAPTER VIII

THE SPLEEN; THE LIFE OF THE RED CELL; THE REGENERATION OF BLOOD

THE FUNCTIONS OF THE SPLEEN

The spleen serves three well recognized purposes, namely, (1) the final destruction of blood cells, (2) the storage of blood and (3) the manufacture of lymphocytes in the lymphoid tissue composing the Malpighian corpuscles (p. 55).

(1) THE RÔLE PLAYED BY THE SPLEEN IN THE DESTRUCTION OF THE BLOOD CELLS

In the pulp of the spleen are to be found relatively enormous mononuclear ameboid cells which have the power to engulf foreign particles of various sorts. They are known as *macrophages* and at times may be seen with fragments of, or even whole erythrocytes within their bodies. These cells belong to the reticulo-endothelial system (p. 78). In certain conditions in which a great destruction of red cells is a feature, immense numbers of these phagocytic cells may be seen loaded with erythrocyte fragments of various sizes. Sometimes merely a dust-like residue (*hemoconia*) containing hemoglobin is all that can be seen of the blood cell. Attempts to demonstrate a blood-destroying function of the spleen by comparative estimates of the corpuscular contents of the arterial (ingoing) and venous (outgoing) bloods have not, on the whole, been very successful. But Mann and his associates have been able, by spectroscopic examination of the arterial and venous bloods, to show a definite excess of bilirubin (iron-free pigment) in the blood of the splenic vein over that of the splenic artery. The bilirubin in the venous blood of other organs was no greater in amount than that in the arterial blood. In diseases with marked red cell destruction, the spleen becomes impregnated with iron and with an iron containing pigment, *hemosiderin*, derived from the hemoglobin of the disintegrated cells. Similar deposits occur in the liver and to a less extent in other tissues.

Though evidence derived from microscopical studies and from bilirubin estimations shows undoubtedly that red cell disintegration occurs in the spleen, it is believed that it is only fragmented, dead, or effete and senile erythrocytes that are disposed of in this way. The organ is not thought to attack healthy circulating cells. It rather

serves as a "grave-yard" than as a "slaughter-house" for the erythrocytes.

(2) THE SPLEEN AS A BLOOD-RESERVOIR

This function was discovered more or less by accident, and the discovery was a by-product, one might say, of researches which were being prosecuted with another aim in view. Barcroft and his party travelled to the Peruvian Andes to make observations upon the phenomena associated with acclimatization to high altitudes (mountain sickness). Blood volume and hemoglobin estimations were made upon the members of the party on board ship from time to time throughout the voyage in order that values at sea level might be obtained with which observations at the higher altitudes later could be compared. As the party reached tropical waters the blood volume as well as the hemoglobin concentrations were found to have increased. Upon passing the Equator and reaching colder regions these values declined again. It was surmised that the changes were due to temperature variations. It was difficult to conceive of a mechanism that could actually manufacture or destroy red cells at such a rate as to produce such rapid changes in blood volume and hemoglobin concentration. It was concluded, therefore, that the extra blood had been released, during the climatic rise in temperature, from some region where it had been stored, and was returned again to the reservoir when the temperature declined. The spleen was suspected of being the reservoir and subsequent experiments proved this to be so.

When guinea pigs were permitted to breathe an atmosphere containing from 0.06 to 1 per cent carbon monoxide, it was found that the blood of the general circulation contained the expected amount of the inhaled gas but the blood of the spleen contained none until a considerable time had elapsed. There was a lag in some cases of 2 hours in the absorption of the gas by the blood of the spleen. When, after the splenic blood had absorbed the gas, the animals were brought into pure air the carbon monoxide disappeared from the systemic circulation much sooner than from the blood of the spleen. These facts could only be accounted for on the assumption that blood had

been held in the spleen out of the general circulation, i.e., in a sort of cul de sac. No difference in the gas content of the bloods in the two regions occurred, however, if strenuous exercise were carried out immediately prior to the inhalation of the gas. This suggested that during exercise the spleen contracted, and expelled the blood that had been held stagnant within its substance. Proof was gained by an ingenious experiment. Metal rods were fastened to the spleen at such points that changes in their position would indicate changes in splenic volume. The animal's abdomen was closed and time allowed for it to recover after the operation. X-ray examinations were then made before and after exercise, when it was found that a pronounced shrinkage of the organ occurred as a result of the exertion. In other experiments the spleen was drawn out of the abdomen and fixed to the abdominal wall which was then closed around the splenic pedicle. The animal recovers after this operation and remains in good health. Direct observations of changes in splenic volume could by this means be made from time to time under different experimental conditions. It has been estimated that in the cat the spleen is capable of expelling during very strenuous exercise a quantity of blood (plasma and cells) equal to one-sixth of the total blood volume, and that the number of red cells discharged might be as much as one-fourth of the body's total supply. The blood of the spleen has therefore a much higher corpuscular content than that of the general circulation. The concentration of the blood in the spleen occurs very rapidly—within a few minutes.

By the liberation of a large number of red cells during exercise the blood is enriched in hemoglobin, and its oxygen carrying capacity as a consequence, increased. In this way the spleen serves an *emergency function*. Its value in an emergency was also shown when normal and splenectomized guinea pigs were exposed to an atmosphere containing a given percentage of carbon monoxide. The animals operated upon succumbed much sooner than the normal ones, and a dose just sufficient to kill the former was not lethal for the latter. There was no difference, however, in the survival time when hydrocyanic acid was used, since this poison does not cause death through any effect upon the oxygen carrying capacity of the blood. In conditions, such as muscular exercise, hemorrhage, carbon monoxide poisoning, etc., or under any circumstances in which the oxygen supply to the tissues falls below their requirements, contraction of the spleen and the expulsion of an

extra quota of blood into the circulation occurs. The necessity automatically brings about its own relief, for lowered oxygen tension is the adequate stimulus for splenic contraction. The stimulus evidently acts not directly upon the spleen but upon the nerve centers, for there is no response to lowered oxygen tensions if the splenic nerves have first been cut.¹

Cannon and Izquierdo have shown that in cats excitement produces an increase of over 25 per cent in the red cell count, which he ascribes to a discharge from the splenic reservoir. Injections of adrenaline, pituitrin, acetylcholine and pilocarpine have a similar effect. Hargis and Mann have demonstrated in dogs that the slightest disturbance in the animal's surroundings, e.g., the banging of a door, or procedures causing minor discomfort to

Fig. 16. Changes in volume of spleen as a result of emotional excitement (after Barcroft). Sketch on left, R, rest; C, dog sees cat. The numbers represent the relative sizes of the dog's spleen. Sketch on right, — . — . — rest; — — — smells cat; hears cat; — — — sees cat; — — — chases cat.

the animal, cause reflex-contraction of the spleen. This is accompanied by increased blood flow through the splenic vein.

The effect of emotional states upon splenic volume are shown in figure 16. The spleen also undergoes spontaneous rhythmical changes in volume which as shown by Barcroft and Nisimaru are responsible for certain low undulations seen in blood pressure tracings. These splenic contractions and the blood pressure waves to which they give rise have a duration of from 25 to 50 seconds (fig. 17). The blood pressure wave is the result

¹ It has been shown by Barcroft and his colleagues that the splenic volume progressively diminishes from about the middle of pregnancy to term. Blood is transferred apparently to the uterine vessels for the nourishment of the fetuses. After the birth of the young the spleen rapidly regains its usual size. In animals in which the spleen has been denervated, pregnancy does not cause a reduction in splenic volume.

of the slight increase in blood volume caused by the splenic contraction, the troughs of the splenic waves which represent the points of minimum splenic volume coinciding therefore with the crests of the waves on the blood pressure tracing. The waves are more pronounced after denervation of the spleen; they disappear after clamping the splenic artery.

The structure of the spleen is suited most admirably for the two functions which have just been considered. In its relaxed condition in the living body it is a large organ—3 to 5 times larger than post-mortem examination would lead one to expect, for the throes of death cause it to contract to minimal proportions. The blood is delivered into the substance of the spleen by fine arterial vessels. Through these the blood floods the

FIG. 17. S.V. = splenic volume. B.P. = general arterial blood pressure. T = time, 5 sec. B = baseline at 40 mm.Hg. Spleen in plethysmograph; *a*, before clamping splenic vessels, *b*, after clamping vessels, *c*, after removal of clamp (after Barcroft and Nisimaru).

splenic pulp and percolates between its cells. It is collected again into venous sinuses whose walls are formed of flattened cells possessing phagocytic proclivities of the highest order (reticulo-endothelial elements). The blood passes freely into the sinuses through numerous perforations in their walls. A certain proportion of the splenic arterioles open directly into the sinuses. The latter are drained by small veins with intact walls which join with similar radicles to form larger venous trunks. The splenic circulation is therefore an open one and a large part of the blood in its passage from the arterial to the venous side traverses the morass of splenic pulp. The flow at ordinary times is very sluggish, and within the venous sinuses the blood may be almost stagnant. Nevertheless within a relatively short time all the red cells in the body are brought into direct relationship with the splenic tissue to pass inspection by the macrophages lurking in the pulp and

lining the sinuses. To these cells the infirm, senile or dying erythrocytes fall a prey.

The capsule of the spleen is provided with *unstriated muscle* fibers which penetrate its substance and are continued along the fibrous trabeculae into the depths of the organ. The distribution of the muscle in this way explains how the spleen is enabled so quickly to alter its volume.

Dotted throughout the spleen, like islands, and surrounded by the pulp are lighter areas of lymphoid tissue. These are the *Malpighian corpuscles*. Many of them, especially in infancy, show a pale central area known as the "germ center." The Malpighian corpuscle (fig. 18) is pierced by a small artery; it is analogous to

FIG. 18. Diagram of the human spleen. (A) artery and vein (V) in a trabecula (T) of the capsule (C); ZA, central artery of the corpuscle of Malpighi (MK); P, small arteries; HA, arteries with a sheath; AK, arterial capillaries which terminate in the sinuses (I) or in the meshes of the reticulum (2); MS, venous sinuses; W, white pulp (from Cajal after Szymonowicz).

similar areas in lymph nodes, and serves the same function, namely the manufacture of lymphocytes. The development of these cells is considered in Chapter XI.

ENLARGEMENT OF THE SPLEEN (SPLENOMEGALY)—SPLENECTOMY

Removal of the spleen in animals as a means of studying its functions with regard either to blood destruction or to blood formation has yielded little definite information. The organ does, however, appear to have an indirect influence upon blood destruction in that it alters the resistance of the red cells to the action of hypotonic solutions and other hemolytic agents. If

the spleen be removed, the erythrocytes are rendered much less fragile as is shown by the reduced power of certain poisons to cause hemolysis. The spleen appears also, under certain conditions at any rate, to cause excessive destruction of blood platelets and even in persons with a normal blood picture splenectomy causes an increase in platelets. The erythrocytes of the blood in the spleen are also more fragile than those of the general circulation.

In *purpura hemorrhagica* (p. 95) removal of the spleen is followed by a rise in the platelet count and amelioration of the symptoms. Also, substances such as anti-platelet serum or diphtheria toxin, which when injected cause platelet destruction, are rendered much less effective if the spleen has been removed. Splenectomy frequently brings about a cure in *hemolytic jaundice* (acholuric jaundice) p. 61. The spleen may be considerably enlarged in *pernicious anemia* but splenectomy exerts no effect upon the course of the disease and is never justified. (It has been mentioned that the spleen does not destroy healthy erythrocytes and the fragility of the red cells is actually decreased in *pernicious anemia*.) In *splenic anemia* (Banti's disease), the spleen is tremendously enlarged, the liver becomes cirrhotic, there are repeated hemorrhages. Splenectomy has been practised with success in this condition. Splenic enlargement is a feature of many other abnormal conditions, such as malaria, Hodgkin's disease, leukemia, etc., but in these benefit does not follow its removal. The organ is also enlarged sometimes enormously in *polycythemia*, but splenectomy fails to cure the condition, and indeed is attended by grave risks to life (Moynihan).

Gaucher's disease is an interesting though rare condition which, commencing usually in childhood, is associated with a colossal enlargement of the spleen. The enlargement is due to hypertrophy and hyperplasia of reticulo-endothelial elements. Masses of very large vesicular cells (Gaucher's cells) filled with a cerebroside called *kerasin* are seen in the lymphoid tissue and venous sinuses of the spleen. Hyperplasia of reticulo-endothelial elements also occurs in other situations, e.g., bone marrow and liver. The disease is due apparently to some disorder of lipid metabolism. Splenectomy is the only effective treatment. *Niemann-Pick's disease* is a somewhat similar condition affecting the reticulo-endothelial system and lipid metabolism. Characteristic cells, known from their appearance as "foam cells," are present in large numbers; they are loaded with an unknown phospholipid material. Subjects of this and the preceding disease are usually children of the Jewish race. *Von Jaksch's disease* occurs in infants and is characterized by splenomegaly, anemia and an increase in the number of white blood cells.

From its position in the portal circulation the spleen is also very susceptible to enlargement, either as a result of mechanical obstruction to the veins or to high venous pressure resulting from cardiac or hepatic disease.

THE LIFE OF THE RED CELL

From the amount of bile pigment which is excreted daily by the liver the conclusion must be drawn that a very large amount of hemoglobin (since this is the sole or at least the main source of bile pigment (p. 459)) is liberated from disintegrated red cells in 24 hours.

There are three possible ways in which erythrocytes might be destroyed in the body: (1) By the macrophages of the spleen, (2) by the action of a hemolytic substance in the blood, (3) through simple wear and tear and disintegration in the blood stream. There is no evidence that hemolysis occurs to any significant extent in normal blood and the phagocytic cells of the normal spleen seem quite inadequate to account for the wholesale destruction of cells which evidently must be going on continually in the body. The work of Rouse indicates that the erythrocytes to a very large extent undergo disintegration in the blood stream as a result of the stresses and strains to which they are incessantly subjected during their passage through the vessels. When it is considered what a delicate structure the red cell is and to what violent treatment it is exposed during its lifetime, this wastage is not surprising. The cells are flung from the heart into the arteries at high velocity. In their voyage around the circulation they are exposed to jostlings and innumerable collisions with one another and with the arterial walls. At times they are forced through channels which are too narrow to permit their passage without marked distortions of their shape; or they may be caught in a fork at the branching of a vessel and become "saddle-bagged" over it. Their membranes are almost continually undergoing alterations in tension as a result of osmotic changes. At last becoming older they are unable to withstand these abuses and undergo fragmentation. Fragments of different shapes and varying in size from that of a half or a quarter of the whole cell, to mere dust-like remnants containing hemoglobin (hemoconia) may be found in the circulating blood, in the spleen and to a limited extent occasionally in other tissues.

It has been estimated that in health about ten million cells are destroyed in this way every second—and of course the same number must be formed afresh by the blood forming tissue. The loss of hemoglobin is about 25 grams daily. The number of red cells and hemoglobin concentration in the circulation at any moment represents the balance struck between blood wastage and blood formation by the bone marrow.

Many attempts have been made to determine

the life-span of the erythrocyte. Ashby used an ingenious method for such determinations in man. This method consists in transfusing compatible red cells into an individual and later examining his blood from time to time for the presence of the foreign corpuscles. The foreign cells are distinguished from the transfused person's own cells by means of the serum of another belonging to a group with which the recipient's cells but not the foreign cells are incompatible² (p. 34). Using this method, it has been found that the life of the average red cell is about 80 days and some survive for over 120 days. The life of the erythrocyte of the dog has been estimated by Hawkins and Whipple at 124 days.

THE REGENERATION OF BLOOD

THE MATERIALS NECESSARY FOR ERYTHROCYTE FORMATION

(a) *The red cell stroma.* It is doubtful whether the materials required for the construction of the framework of the cell, e.g., nucleoprotein, globulin, lecithin and cholesterol are ever lacking. The body possesses large supplies of these materials and an ordinary diet contains them in adequate amounts.

(b) *Hemoglobin* is added to the red cell only after the cell's development has progressed to a certain stage (p. 83). The complete history of hemoglobin in the body has yet to be written, but the researches of Whipple and his associates indicate that the body can synthesize the pyrrol nucleus for the manufacture of the blood pigment. When hemoglobin was given intravenously to anemic dogs, the animals' hemoglobin was increased by an amount equal to that injected. At the same time the excretion of bile pigment was increased by a corresponding amount. This apparently paradoxical result is interpreted in the following way. The pyrrol of the injected hemoglobin is excreted as bilirubin, while the globin part of the molecule is utilized for the production of new hemoglobin, the pyrrol groups of which must therefore be derived from some other source—food or body tissue—and synthesized to porphyrin. It is possible that food porphyrins differing from that in hemoglobin can be broken down into their constituent pyrrol groups which are then rebuilt into proto-

² Thus if corpuscles of Group O are transfused into a person belonging to Group A or AB then, when the recipient's blood is mixed outside the body with Group O serum, the recipient's corpuscles but not the foreign cells will be agglutinated.

porphyrin (p. 40). The supposed value of spinach and other green vegetables as hemoglobin builders has suggested such a process. Yet according to Whipple and his associates chlorophyll is not utilized by the dog for hemoglobin synthesis.³ It has already been pointed out (p. 41) that heme (porphyrin + iron) is a universal material and is present in the great majority of food stuffs. So here it might be supposed was a source of an almost unlimited supply of the necessary pigment element. Yet this compound cannot be split by the digestive secretions and it is generally agreed that iron so combined can not be utilized for hemoglobin

TABLE 9
Hemoglobin production influenced by diet

DIET, GRAMS DAILY	HEMOGLOBIN PRODUCTION (TWO-WEEK FEEDING PERIOD)
	grams
Bread 400.....	3
Milk 450, Bread 400.....	3
Cream 100, Bread 400.....	10
Butter 100, Bread 350.....	15

synthesis. The globin necessary for the completion of the hemoglobin molecule is available in most meats, and Whipple and his associates have found that this protein is well utilized for hemoglobin synthesis, yielding for each 100 grams fed from 30 to 40 grams of blood pigment. Hemoglobin or globin or a digest of the latter when given intravenously forms hemoglobin almost gram for gram. They found that as compared with the

³ Hughes and Latner found that whereas large doses of chlorophyll do not favor hemoglobin regeneration, small quantities (15 mgm.) are definitely stimulating. The larger doses they believe exert a toxic action (possibly due to the magnesium content of the pigment) upon the bone marrow.

porphyrin part of the molecule globin was of much greater importance for hemoglobin regeneration; globin apparently is a limiting factor in hemoglobin synthesis. Upon a diet low in protein but adequate in iron hemoglobin regeneration was minimal. Certain amino-acids, especially proline and threonine were found to increase hemoglobin regeneration above the basal level, which suggests that they are used for the synthesis of globin. Histidine which constitutes 8 per cent of the globin molecule is, contrary to expectation, less effective.

Whipple, Hooper and Robschait carried out a series of experiments upon animals made anemic through repeated bleedings, and tested their power to regenerate hemoglobin when fed upon various diets. Meats were found to be the most potent for this purpose. Carbohydrates in the form of bread and sugar were found to be ineffective. In fact they had actually a definitely depressing effect upon the hemoglobin repair process, for animals regenerated their blood more rapidly when starved than when fed upon a bread and sugar diet. In explanation of this fact Whipple suggested that the starved animal drew upon its tissues to supply the basic elements for hemoglobin synthesis, whereas carbohydrate food on account of its well-known protein-sparing effect (p. 553) prevented the tissues from being utilized in this way. Infection or very severe liver damage markedly depresses hemoglobin regeneration in anemic dogs. The depressing effect upon regeneration of hemoglobin which is seen in the bile and Eck fistula animals is apparently due to interference with liver function (defective protein synthesis) and to the reduction in iron absorption.

These workers found that, of all protein foods, liver was by far the most effective for blood regeneration. Next in order came kidney and chicken gizzard. Milk had little regenerating effect. Table 9 shows the comparative values of the various articles of diet. A bread mixture consisting of potato and wheat flour, bran, sugar and the necessary salts and vitamins was used as the basal diet. This was practically inert so far as the regeneration of hemoglobin was concerned. The article to be tested was added to this basal diet.

The animals (dogs) were rendered anemic by three or four successive bleedings until the hemoglobin had been reduced to 30 per cent of the normal. The animal was then placed upon the diet to be tested, and was bled from time to time in order to maintain the hemoglobin at the original level of 30 per cent. The amount

of blood removed expressed in grams of hemoglobin gave a direct measure of the amount of pigment regenerated in a given time.

Cobalt has a powerfully stimulating effect upon red cell production and in repeated doses may induce polycythemia (p. 10).

The clinical application of these laboratory findings will be considered in the next chapter.

IRON METABOLISM

Being an essential constituent of the hemoglobin molecule, this mineral must be available in adequate amounts in order that normal blood regeneration shall occur. A diet deficient in iron leads to a certain type of anemia. Iron provides the keystone for hemoglobin construction; unless it is supplied in appropriate amounts the maturation of the red cells is retarded, and the numbers discharged from the bone marrow into the general circulation, reduced.

Absorption, storage and excretion of iron

Iron is absorbed throughout the entire intestinal tract, but to the greatest extent in the upper part of the small intestine. The absorption is by way of the blood. After absorption the metal disappears rapidly from the circulation, being stored in the liver and to a less extent in the spleen and kidney. Liver iron is readily increased by iron feeding or injection. Only minute quantities of iron are detectable in the plasma (0.1 to 0.3 mg. per 100 cc.) under ordinary circumstances, the great proportion of the iron of the body being present in the red cells. A smaller quantity is present in the muscle (myoglobin, cytochrome, etc.). Whole blood contains from 45 to 50 mg. per cent and the total quantity in the adult human body is about 4 grams. Iron is present in the blood in three forms, (a) plasma iron, already mentioned and which represents mainly iron in transit from the intestinal tract to the depots, (b) iron combined with hemoglobin, which accounts for from 92 to 98 per cent of the total, and (c) from 2 to 8 per cent which is liberated by the action of mineral acids and called for this reason "easily split off" iron. This fraction is attached to the erythrocyte, and is derived apparently from an intermediary compound formed in the breakdown of hemoglobin.

It is commonly stated that iron is excreted almost exclusively through the intestinal wall, mainly through the wall of the colon. The evidence for this statement is not, however, very

convincing. If it were true one would expect an increase in fecal iron in conditions associated with the excessive breakdown of red cells, which is not the case. Also when iron is injected into rats almost all can be recovered from the organs, none appearing in the feces. Only very minute amounts of iron appear in the urine and bile and it is probable that correspondingly small quantities are excreted by the bowel. According to McCance and Widdowson, the iron content of the body is controlled through the *regulation of absorption* and not by excretion. Several factors influence iron absorption, e.g., the acidity of the gastric juice and especially the *reserve stores of iron* in the body. Balfour and his associates found, for example, that from 2 to 10 times the usual quantity of radioactive iron⁴ was absorbed in the later months of pregnancy when the iron stores are low. The absorption of iron is increased by chlorophyll, by bile pigments, by calcium and by vitamin C, and diminished by excessive secretion of mucus. Iron is therefore largely a "one-way" element. It is absorbed, the absorption being conditioned by several factors, but, under ordinary circumstances, it is excreted only in minute amounts.

Besides its well known function as an essential element in the hemoglobin molecule, and as a constituent of other respiratory pigments, iron appears to play a rôle in the nutrition of epithelial surfaces. Abnormal nail growth, glossitis, fissures around the corners of the mouth and localized thickening of the mucous lining of the esophagus leading to dysphagia occur in anemias due to iron deficiency, and are cured by iron administration.

Fifteen to twenty milligrams (p. 668), is the daily iron requirement of the adult.

The erroneous belief has been current in the past that only iron in organic combination could be absorbed and utilized for the construction of hemoglobin. Whipple and associates found that in the posthemorrhagic anemia of dogs iron in any soluble form was utilized, and Elvehjem, Hart and Sherman found that inorganic iron in the form of ferric chloride, pyrophosphate, hypophosphite and glutamate was utilized. The idea that only organic iron is available for hemoglobin synthesis probably arose from the fact that in iron-containing foods (e.g., egg-yolk) which were recognized to be efficient hemoglobin formers, the inorganic iron is

masked. It is now known that the truly organic iron of such foods, namely that combined in heme, is not available, since it is not released by peptic or tryptic digestion, whereas the inorganic iron which may represent 50 per cent or more of the total iron of the food is utilizable. This latter after conversion to the ferrous form is estimated by the dipyrindyl method. During digestion the inorganic iron of the food, which is in the ferric state, gives up oxygen to oxidizable substances in the alimentary tract and is converted, in part at any rate, to the ferrous state; as such only is it absorbed. Animals fed dipyrindyl become anemic since the ferrous iron is rendered insoluble.

In certain anemias, especially when the gastric juice lacks HCl, which normally aids in the liberation of iron from the food, and facilitates its conversion to the ferrous form, compounds of ferrous iron, e.g., ferrous chloride⁵ and ferrous carbonate are specific in their effects, causing a discharge of reticulocytes from the bone marrow and an increase in the red cell count.

THE SIGNIFICANCE OF COPPER

This metal is believed to act as a catalyst in some stage of hemoglobin synthesis. It does not itself enter into the structure of the hemoglobin molecule. Waddell, Elvehjem, Steenbock and Hart found that in young rats rendered anemic by being placed upon a diet of whole cow's milk, iron alone failed to promote hemoglobin regeneration.⁶

⁵ Ferric iron, e.g., reduced iron or iron and ammonium citrate, must be given in relatively very large amounts since only a small proportion of it is converted to ferrous iron in the gastro-intestinal tract. When reduced iron is dissolved in dilute hydrochloric acid, ferrous chloride is formed. The administration of a mixture of this sort has been strongly advocated by Lucas and Henderson (Can. Med. Ass. Jour., 1933, 28, 298).

Iron is sometimes given parenterally but it is to be remembered that when free in the blood stream the metal exerts a toxic effect. The lethal dose for an animal is 30 to 60 mg. per kilogram. It has been shown by Castle and associates that in hypochromic anemia a daily dose of 32 mg. of iron in the form of iron and ammonium citrate, administered parenterally, is utilized completely in the formation of hemoglobin. It was also shown that 32 mg. of iron administered in this way is equal to 1000 mg. given by mouth. This is merely a further demonstration of the fact that only a very small proportion of ferric iron is converted into the absorbable form in the alimentary tract and should not be taken in any way to imply that iron administered by injection has any advantage over ferrous compounds given in adequate amounts by mouth.

⁶ Some experimenters have obtained a certain degree of hemoglobin regeneration with iron alone, though the rate of regeneration was much increased by the addition of copper.

⁴ Radioactive iron has proved a valuable tool in studies of iron metabolism since it can be readily traced in the body tissues and fluids. It is prepared by bombardment of Fe⁵⁸ isotope with deuterium.

When the iron was supplemented by a very small quantity of copper, blood regeneration was induced. Manganese exerts a similar though less pronounced supplementary effect. The liver is the main storehouse for copper and minute amounts (0.1 to 0.5 mg.) are present normally in blood.

Though anemia due to copper deficiency is unknown in man, a severe and even fatal anemia due to the lack of this metal may occur in farm animals, e.g., the "falling sickness" of South African cattle.

Hemochromatosis

This is a disturbance in iron metabolism in which extensive deposits of an iron-containing pigment called *hemosiderin* are found in the liver and other tissues. The Kupffer cells (p. 80) are loaded with pigment. Deposits are also found in the parenchymal cells. The disease is not due, as was believed at one time, to

increased blood destruction. The total iron content of the body is greatly increased; it may be 10 times the normal amount. A second yellow iron-holding pigment known as *hemofuscin* is also sometimes present in the connective and muscular tissues. Other features of the condition are *bronzing of the skin*, *cirrhosis of the liver*, *sclerosis of the pancreas* with diabetes (bronzed diabetes). The cause of the condition is unknown, though it has been ascribed by Mallory to chronic copper poisoning. According to this observer the excretion of iron is interfered with; the hemoglobin liberated, as a result of the normal wastage of red cells, combines with copper to form *cuprohemol*. The foreign metal is later freed and hemofuscin formed. This is then converted by tissue enzymes to hemosiderin which induces necrosis and fibrosis of the tissue at the site of its deposition.

Hemosiderosis is the term applied to the deposit of hemosiderin in the tissues which occurs as a result of the excessive breakdown of red cells in malaria and hemolytic types of anemia. It may be looked upon simply as an exaggeration of the normal process of iron deposition.

CHAPTER IX

THE ANEMIAS

CLASSIFICATION

We have seen that in health the population of red cells and the concentration of hemoglobin in the blood are kept at normal levels by a nice balance between the new formation and the wastage of erythrocytes. Anemia results when the balance is tipped one or the other way, i.e., by a defect of blood formation or an increase in blood wastage. So the anemias may be classified broadly into (A) *those associated with blood loss or increased blood destruction* and (B) *those due to defective blood formation*.

(A) *Anemias due to blood loss or increased blood destruction*. Among this group are included those types of anemia resulting from:

- | | |
|--------------------------|---|
| Post-hemorrhagic anemias | (a) Hemorrhage |
| | <ul style="list-style-type: none"> i. Acute ii. Chronic, as a result, for example, of peptic ulcer, uterine bleeding, ankylostomiasis (hook-worm disease) purpura, etc. |
| Hemolytic anemias | (b) Red cell destruction, as a result of: |
| | i. Chemical hemolytic poisons, lead, arseniureted hydrogen and certain coal tar derivatives. |
| | ii. Specific infections, e.g., malaria, septicemia. |
| | iii. Abnormal structure of the red cells, e.g., hemolytic or acholuric jaundice and sickle cell anemia. |
| | iv. An auto-agglutinin or endogenous hemolysin of unknown nature, e.g., paroxysmal hemoglobinuria (p. 50) and the acute hemolytic anemia of Lederer. |

In the hemolytic group the increased blood destruction is manifested by a rise in the concentration of bile pigment in the plasma which gives an indirect van den Bergh reaction (p. 465), a greater excretion of pigment in the urine (urobilin) and feces, and the deposit of an iron-containing pigment in the liver and other tissues (hemosiderosis, p. 60). There is frequently jaundice of a slight or moderate grade.

Sickle-cell anemia is believed to be due to blood

destruction as a result of a congenital anomaly of the red cells. In this type which occurs almost exclusively in negroes, elongated crescent or sickle-shaped erythrocytes some 15μ or so in length are a characteristic feature. Such cells are found in the blood of a high percentage of negroes (8 to 9 per cent) though only relatively few, 1 in 40, of these develop anemia.

Hemolytic or acholuric jaundice. The chief features of this form of anemia are a *familial tendency*, *jaundice* and high incidence of pigment gall stones, *spheroid erythrocytes* (i.e., the diameter of the cells is reduced but their thickness increased, their volume being approximately normal), *reticulocytosis* up to 60 per cent or more of the total red cell population, increased *fragility* of the cells and *enlargement of the spleen*. Splenectomy is usually followed by the disappearance of jaundice, a return of the red cell count to normal and a marked reduction in the reticulocytosis. The spherocytosis gradually disappears and with it the increased fragility of the erythrocytes. These facts indicate that disordered function of the spleen is not the primary cause of the condition. The cause of the hemolysis is unknown though it may be due simply, as in certain other anemias, to the reaction of the macrophages of the spleen to the defective cells produced by an abnormally functioning bone marrow. Others believe that an endogenous hemolytic agent is responsible, a view which receives support from the experiments of Dameshek and Schwartz in which a hemolytic serum produced by the injection of guinea-pig's cells into rabbits was employed to produce anemia. The injection of this anti-guinea-pig hemolytic serum into guinea-pigs caused a profound drop in the red cell count and the appearance of cells with spheroid shape, increased fragility and a reticulocytosis. These observers believe that the greater fragility of the red cells is simply a function of their increased thickness and that spherocytosis is the primary change—a reaction of the bone marrow to excessive destruction of red cells caused by a circulating hemolysin.

(B) *Anemias due to defective blood formation*. This group comprises anemias resulting from:

- (a) *Nutritional anemias*. i. *Iron deficiency*—hypochromic, microcytic anemias. The deficiency may be due either to the excessive loss of iron from the body as in chronic hemorrhage or to an inadequate quantity of this element in the diet (p. 62).
- ii. *Protein deficiency*, though in itself a less common cause of anemia, is not infrequently a contributory factor. iii. *Lack of vitamin C* or of certain factors of the *B complex*, e.g., pyridoxin.

- (b) *Lack of or failure in the utilization of the specific anti-anemic factor*—Addisonian pernicious anemia and certain related hyperchromic macrocytic anemias with a megaloblastic type of bone marrow (p. 64).
- (c) *Macrocytic anemias (hypo- or hyperchromic) with normoblastic bone marrow.*
- (d) *Toxic agents which induce aplasia of the bone marrow or depress its function—aplastic anemias.* Among such agents are benzol, arsphenamine, radium, X-rays and sometimes bacterial and syphilitic toxins. This is the most severe type of anemia. The red marrow is greatly reduced in amount, being replaced by fatty tissue. Blood formation is profoundly depressed. Anemia of the aplastic type may also result from exhaustion of the bone marrow following a long period of overactivity induced by some other type of anemia, or may appear without a known cause (*idiopathic aplastic anemia*, p. 69).

The anemias associated with certain conditions, e.g., nephritis and chronic infections, are believed to be due to a relatively mild degree of depression of bone marrow function. In such types, destruction of red cells by toxic substances (metabolic or bacterial) may also be a contributory factor.

The cause of *splenic anemia* (Banti's) is unknown; it is therefore difficult to fit this type into either of the preceding categories. According to some there is increased blood destruction, but the chief factors appear to be depressed marrow function and the loss of blood resulting from repeated gastro-intestinal hemorrhages. An anemia very closely resembling Addisonian or true pernicious anemia results from infestation with the fish tapeworm, *Diphyllobothrium latum*. A toxin derived from the worm itself is a factor but apparently not the sole one in the development of the anemia. It is exceedingly rare on this continent.

The following indices calculated from the hemoglobin concentration, red cell count and cell volume of a specimen of blood are employed to express the characters of the individual cells in the different types of anemia.

The *color index*. This is a numerical expression of the hemoglobin content of the individual red cells. It is obtained by dividing the hemoglobin value in grams per 100 cc. by the red cell count, both values being expressed as percentages of the normal. (The normal weight of hemoglobin per 100 cc. is taken as 14.5 grams and the red cell count as 5 million.) Thus, if the hemoglobin is 60 per cent of normal and the red cell count 50 per cent, then $\frac{60}{50} = 1.2$ color index. But if the hemoglobin percentage is reduced to a greater degree than the red cell percentage the index will be

less than unity. That is, each red cell contains less than its normal quota of hemoglobin. On the other hand, the hemoglobin concentration of the blood may be greatly reduced but if the reduction runs parallel with the reduction in red cell percentage the index will have the normal value of 1.0.

The *iron index* is obtained by dividing the number of milligrams of iron in 100 cc. of blood by the first three figures of the red cell count. The normal value is between 9.50 and 10.00. Thus if there are 50 mgm. of iron in 100 cc. of blood and the red cell count is 5,000,000, the iron index is $\frac{50}{5.00} = 10.00$. Sometimes

what is known as the *iron color index* is employed. This is the quotient obtained by dividing the iron content expressed as a percentage of the normal by the percentage of red cells. Thus

$$\frac{\text{Percentage of iron}}{\text{Percentage of red cells}} = \text{iron color index}$$

The *volume index* is an expression of the average size of the red cells in a given sample of blood as compared with the average normal size. It is obtained by dividing the volume of the red cells (as determined by the hematocrit and expressed as a percentage of the volume of a healthy person) by the number of red cells as a percentage of the normal, (the normal being taken as 5 million). Thus, if the volume of cells in the sample is 40 cc. per 100 cc. of blood, i.e. 90 per cent of the average normal volume (which is 45 cc.) and the red cell count is 4.5 million, which is also 90 per cent of the normal, then the volume index is $\frac{90}{90} = 1$. If, on the other hand, the volume is say 70 per cent of the normal and the red cell count 50 per cent then $\frac{70}{50} = 1.4$ volume index. That is, the average size of the red cells is greater than normal.

The *saturation index*. This is an expression of the concentration of hemoglobin in the red cell and is obtained by dividing the figure for the weight of hemoglobin by the figure for the packed cell volume, both figures being percentages of the normal. Thus, if the weight of hemoglobin is 11.6 grams per 100 cc. (i.e., 80 per cent of normal) and the packed cell volume is 40 (i.e., 88 per cent of normal which is taken as 45) then, $\frac{80}{88} = 0.90$ saturation index.

HYPOCHROMIC MICROCYTIC ANEMIAS—IRON DEFICIENCY

In this group the essential defect is one of hemoglobin formation. The hemoglobin percentage of the blood is reduced to a greater extent than the number of red cells. These, indeed, may show only a slight reduction. The color index is therefore considerably below the normal, which means that each red cell has received less than its normal

quota of pigment. The erythrocytes are also smaller than normal, so the volume index is also low. The low color index is in part the result of the smaller size of the red cell but also of a reduced concentration of pigment throughout the red cell's substance. The saturation and iron indices are therefore also lowered. Some of the corpuscles are so pale that they resemble "ghosts" (p. 48) or only the peripheral zone of the cell is colored (anisochromasia). (See figs. 19 and 20, and frontispiece.)

Iron deficiency is considered to be the essential cause of the anemias belonging to this class. The deficiency may result from an inadequate amount of iron in the diet or from defective absorption of the metal from the food.

Chlorosis is a type of hypochromic anemia which until the last 40 years or so was commonly seen in girls and young women between the ages of 16 and 22 years. It received its name from the peculiar greenish pallor of the skin (green sickness). There was usually hyperchlorhydria. The disease is now rare possibly owing to the more adequate diets of the present generation.

HYPOCHROMIC ANEMIA WITH HYPOCHLORHYDRIA OR ACHLORHYDRIA (ALSO CALLED IDIOPATHIC HYPOCHROMIC ANEMIA)

Some believe that the failure of gastric function is the primary cause of this type. The hydrochloric acid of the gastric juice is normally an important factor in the liberation of iron from the food and in its conversion to the ferrous state. These are necessary preliminaries for its absorption. According to Davidson and Leitch the hypochlorhydria is merely an accessory factor in the production of the iron deficiency, the iron intake being also below the normal. In the experience of these observers, the diets of patients showing this variety of anemia were poor in first class protein, milk and vegetables and contained about half the minimal daily iron requirement of from 15 to 20 mgm. Repeated small hemorrhages or excessive menstrual losses are often contributory factors. It is seldom that one or more of the causes enumerated cannot be detected and for this reason the title "idiopathic" as applied to this type of anemia is scarcely appropriate. Hypochromic anemia sometimes follows operation for the removal of a large section of the stomach.

HYPOCHROMIC ANEMIA WITHOUT HYPOCHLORHYDRIA

Hypochromic anemia with normal gastric acidity also occurs and like the preceding is due to iron deficiency. It occurs most frequently in women

of childbearing age when the dietary deficiency is aggravated by the losses of iron incident to menstruation or repeated pregnancies. Davidson has recently emphasized the need for larger amounts of iron during this period in women.

ANEMIA OF INFANTS

The fetus accumulates a store of iron in the liver in the later months of gestation which serves as a reserve which is drawn upon for the manufacture of hemoglobin in infancy. The high red cell concentration (p. 8) with which the infant comes into the world also contributes to the iron reserves. In the normal infant the iron stores are sufficient for the manufacture of hemoglobin for the first six months or so. Growth, however, makes heavy demands upon the iron supplies and after the first half year it is necessary to provide a diet which will contain adequate amounts of iron in order to guard against the development of anemia of the hypochromic type. Milk, it will be recalled, is very poor in both iron and copper. The development of anemia in milk-fed rats has been mentioned and the anemia of sucklings is a problem in the breeding of farm animals. If the iron stores are deficient at birth as in premature infants or as a result of maternal anemia, anemia may occur in the very young infant.

The hypochromic anemias respond in a spectacular fashion to the administration of inorganic iron (e.g., ferrous chloride, ferrous carbonate, etc., see p. 59). The administration of copper is rarely necessary since this occurs in sufficient quantity in the diet and as an impurity in iron preparations.

PERNICIOUS ANEMIA (ADDISON'S ANEMIA) AND RELATED MACROCYTIC ANEMIAS

Pernicious anemia is due essentially to a defect in the formation of the red cells; hemoglobin synthesis is unaffected.

The CHIEF FEATURES of the blood picture are:

(1) *Great reduction* in the number of red cells and consequently in the hemoglobin percentage. The blood count in a very severe case may be no more than 10 per cent of the normal.

(2) The red cells are reduced in number below the normal to a greater extent than is the hemoglobin percentage. The *color index* is therefore *raised* above normal as are also the saturation, iron and volume indices.

(3) Large cells—the average diameter of the cells is increased to between 8 and 9 microns and exceptionally large cells called *macrocytes* are plentiful. The average volume of the individual red cells (figs. 19 and 20) is

about 135 cu. microns (normal about 90 cu. microns). *Normoblasts* and *megaloblasts* may also be seen. The reticulocytes are around 3 per cent.

(4) The total number of leucocytes is reduced but the lymphocytes are relatively increased.

(5) Great variation in the size of the cells—*anisocytosis*, the cells varying from those smaller than normal to the large cells mentioned above. *Poikilocytes* are moderate in number.

(6) Increase in iron and bilirubin of the plasma; increased excretion of pigment (urobilin)—indirect van den Bergh.

(7) Blood volume reduced mainly as a result of the red cell diminution, the plasma volume being around the normal level.

(8) Fragility of the red cells usually slightly reduced.

OTHER FEATURES.

(1) The red bone marrow is hyperplastic. It extends into the shafts of the bones displacing the yellow marrow and even the bony walls may be eroded. Upon microscopical examination the marrow shows megaloblasts and other immature forms in large numbers (see p. 84).

(2) Achlorhydria almost always exists.

(3) Sore tongue—*glossitis*.

(4) Chronic combined degeneration of the cord.

(5) Urobilin appears in the urine in severe cases; and in all those in which plasma bilirubin is increased urobilinogen is in excess in the feces. In health from $\frac{1}{140}$ to $\frac{1}{340}$ of the total amount of hemoglobin in the blood is excreted daily as urobilinogen. In pernicious

anemia $\frac{1}{10}$ of the total hemoglobin may be excreted as urobilinogen. Hemosiderin deposits (p. 60) occur.

(6) The disease shows remissions and relapses. During the remissions, the blood picture approaches the normal and the percentage of reticulocytes increases—*blood crises*. During the relapses, the characteristic hematological features of the condition are exaggerated.

The essential factor in the production of pernicious anemia is not believed to be increased blood destruction, but rather a defect in blood formation—the reversion of the bone marrow to a more primitive type of erythropoiesis (see p. 83). Increased blood destruction undoubtedly occurs as evidenced by the rise in plasma bilirubin but it is a secondary effect. The abnormal erythrocytes probably stimulate the phagocytic activities of the reticulo-endothelial cells (p. 78) in the spleen, liver and elsewhere. Since the fragility of the red cells is reduced rather than increased it would not appear that they disintegrate more readily in the blood stream (see p. 56). The discovery of an anti-anemic principle in liver and subsequent re-

searches arising from the employment of this principle in the treatment of pernicious anemia has shed a flood of light upon the nature of the disease.

TREATMENT WITH LIVER, LIVER EXTRACT AND GASTRIC TISSUE

In 1926 Minot and Murphy inspired by the laboratory finding of Whipple and his associates, namely, that liver was the most effective article of diet for the treatment of anemia in dogs, tried the effect of adding liver to the diet of pernicious anemia patients. The spectacular success which followed this treatment is well known and today lightly cooked liver (from $\frac{1}{2}$ to 1 pound per day) or liver extract is recognized as a specific for the disease. Kidney tissue was shown to have a similar though less pronounced curative effect. The anti-anemic (or hematinic) principle is contained in the non-protein fraction of liver. Its chemical nature is not known precisely¹ but it is free from lipids, protein and iron. The extract may be given by mouth or intramuscularly. Its action is more rapid and at least 30 times more potent when given by the parenteral route. It may be mentioned here that Wilkinson found that the anti-anemic principle was present in normal human liver and in the livers of pernicious anemia patients who had received specific treatment, but was absent from the livers of untreated subjects of the disease.

The production of the anti-anemic principle, gastric (intrinsic) and extrinsic factors

As already mentioned, achlorhydria is an almost invariable accompaniment of pernicious anemia. The significance of this fact was demonstrated in

¹ Dakin and West reported a few years ago that a commercial extract which they examined contained, after purification, an aminohexose similar to glucosamine, and the amino acids, lysine, arginine, glycine, leucine, hydroxyproline and aspartic acid. The aminohexose yielded pyrrol groups upon condensation with acetylacetone and ammonia, and treatment with alkali (Journ. Biol. Chem., 1935, 109, 489).

More recently Karrer has analyzed a highly purified preparation. He reports that it is acetone-insoluble and contains tryrosine and arginine, but is free from phenylalanine, proline, hydroxyproline, glycine, tryptophane and histidine.

The liver possibly contains at least one other hemopoietic substance besides that effective in pernicious anemia. Wills produced a macrocytic hyperchromic anemia in monkeys by means of dietary defects which failed to respond to highly purified liver extracts, but were cured by crude liver preparations or by yeast, marmite, wheat germ or liver, all of which are rich in the vitamin B complex. The nature of this material, though apparently related in some way to the vitamin B complex, is unknown.

1929 by Castle who found that the gastric contents of a normal person during the digestion of meat were curative when fed to a subject of pernicious anemia. Later Castle and his associates showed that pure gastric juice obtained from a normal person by the administration of histamine when incubated with beef-steak produced the curative material. The active principle was not produced when beef was incubated with gastric juice of a patient with pernicious anemia. The production of the anti-anemic principle is not due to the action of hydrochloric acid, pepsin, rennin or lipase but to the presence of an enzyme-like substance which acts at a pH of 7 (the optimal pH for the action of pepsin is 1.6). Just before this, Sturgis and Isaacs found that gastric tissue contains the material necessary for the formation of the anti-anemic factor, it being, like liver itself, effective in

acts upon a material in certain articles of diet to produce the specific principle. Castle refers to the gastric material as the "intrinsic" factor and to the dietary precursor as the "extrinsic" factor.

FIG. 19. Red-cell-diameter distribution curves in simple achlorhydric anemia and in pernicious anemia compared with the normal (after Haden; see also fig. 20).

the treatment of pernicious anemia. Desiccated de-fatted hog stomach is now employed as an alternative to liver or liver extract for oral administration. The gastric factor is less stable than the liver principle, being destroyed by temperatures above 45°C. and by prolonged digestion with pepsin or trypsin. In the hog, the intrinsic factor is produced by the mucosa of the pyloric and cardiac regions of the stomach and the commencement of the duodenum, i.e., regions which secrete an alkaline juice (pyloric, cardiac and Brunner's glands). In the human subject the intrinsic factor, according to Fox and Castle, is formed in the fundus of the stomach; none is found in the pyloric region nor in the duodenal secretions.

Two factors are concerned therefore in the production of the anti-anemic principle. An enzyme-like substance in healthy gastric juice or in the stomach tissue of man and certain animals which

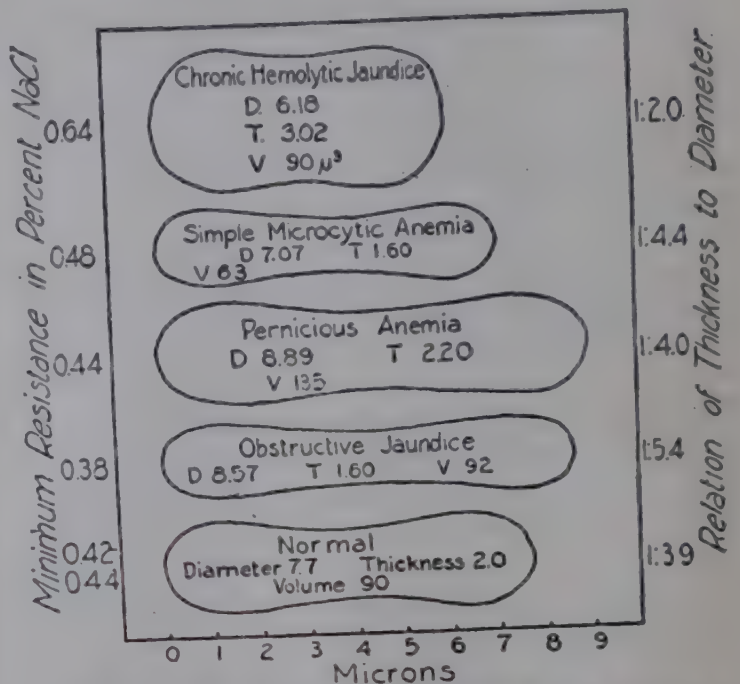

FIG. 20. Red cell diameter, thickness and volume in various clinical conditions compared with the normal (after Haden). D, diameter; T, thickness; V, volume.

FIG. 21. Diagram to illustrate the factors responsible for normal erythropoiesis.

The theory which fits these facts best and relates them to the cure of pernicious anemia is the following. In health the essential anti-anemic principle is derived from food through the action of the "intrinsic" (gastric) factor upon an "extrinsic" factor contained in the diet. The anti-anemic

principle so formed is stored in the liver and possibly other organs, to be drawn upon for the maintenance of normal activity of the erythropoietic tissue (bone-marrow). Pernicious anemia follows if the essential enzyme is absent from the gastric juice.² The anti-anemic principle can therefore be given pre-formed as in liver or liver extract, or gastric tissue and a well-balanced diet can be given from which the patient manufactures his own supplies (fig. 21).

A characteristic lesion is found in pernicious anemia which readily explains the achlorhydria and the lack of the intrinsic factor. The fundus and body of the stomach show atrophy of the mucosa and extreme thinning of all coats. The gastric glands are almost completely destroyed; the muscular coat is atrophic. The pyloric region, which does not produce the intrinsic factor, is normal. One would be led to expect that total gastrectomy in man would be followed by pernicious anemia, yet this is not the case. Only seldom has such a result been reported. The hypochromic type is more frequently a sequel of gastrectomy. Even removal of the entire stomach from dogs is not followed by pernicious anemia. The reason that pernicious anemia does not follow removal of the entire stomach has received no entirely satisfactory explanation. The most probable reason is that the survival time (1–2 years) following the operation in man (usually for carcinoma) is too short for the development of the disease.

The nature of the "extrinsic" factor

Castle found that when autolyzed yeast was acted upon by normal gastric juice the anti-anemic factor was produced. Autolyzed yeast alone was ineffective. He concluded that the extrinsic factor was either vitamin B₂ or a substance closely related to it. It has been shown, however, by Wills that egg-white and other sources of B₂ when acted upon by normal gastric juice do not yield the anti-anemic principle; therefore, though beef, rice polishings, wheat germ and marmite are rich sources of the extrinsic factor, this is not vitamin B₂.

Though anemia of the pernicious type is most commonly due to the absence of the intrinsic

² The foregoing theory implies, of course, that the gastric defect is the direct cause of the blood condition. Yet, though achlorhydria is present in about 5 per cent of persons, only a small proportion develop pernicious anemia; indeed the hypochromic (p. 63) type of anemia is more likely to result. The probable reason is that in the cases of achlorhydria in which pernicious anemia does not occur, the intrinsic factor is not lacking. Some observations of Castle, who found the intrinsic factor present in cases of achlorhydria without anemia, are in accord with this explanation.

factor, it quite obviously could also result from (a) lack of the extrinsic factor in the diet, (b) failure of the anti-anemic principle after its production in the stomach to be absorbed from the intestine, (c) inability of the liver to store the principle, or (d) failure of the latter to be utilized by the hemopoietic tissues. It appears that any one of these stages in the hemopoietic mechanism may be interfered with and an anemia of the pernicious type result. Thus, in *sprue* (steatorrhea, p. 657) an anemia of this type occurs which is attributed to failure of absorption of the hemopoietic factor. Anemia of the same type occurs in certain other intestinal diseases or when the gastric contents are short-circuited into the colon through a gastrocolic fistula. An anemia is seen in the tropics, chiefly in India, which has been attributed to a lack of the extrinsic factor in the diet. But an anemia closely resembling this tropical variety has been produced in monkeys which, as stated in a footnote on page 64, is cured by a crude liver extract but not by one that is highly purified, suggesting that some instances, at least, of the tropical disease may also be due to the lack of a second hemopoietic substance in liver. In very severe *hepatic disease* a macrocytic anemia may develop which is attributed to a failure in storage of the hematinic principle;³ the *pernicious anemia of pregnancy* is probably due to exhaustion of the principle owing to the heavy drains upon the maternal supplies for fetal hemopoiesis. Lack of hydrochloric acid in the gastric juice and a diet lacking the extrinsic factor may be contributory causes. An anemia with a blood picture identical with that of pernicious anemia has been described which does not respond to treatment with liver extracts. It is due apparently to a defect in the utilization of the anti-anemic principle, for the livers of subjects of the disease contain the latter in adequate amounts. The term *achrestic* (Wilkinson) has been applied to this very rare form.

The response to liver or gastric tissue

The anti-anemic principle acts upon the bone marrow, restoring the blood-forming processes to normal. The maturation of the erythrocytes is hastened, the primitive cells of the marrow—megaloblasts—disappearing to be replaced by cells of later stages of development, e.g., late erythroblasts and normoblasts (see p. 84). This specific

³ It has been reported, however, that in some of these cases at least, the liver contains adequate amounts of the hematinic principle. The cause of the macrocytic anemia in these instances is unexplained.

effect of the active principle has been demonstrated by Sabin who found that the addition of liver extract to the early chick embryo accelerated the division and maturation of the primitive megaloblastic cells of the blood islands. Müller demonstrated a corresponding effect upon the bone marrow of pigeons. When these birds are starved the marrow becomes aplastic but subsequently, when a diet of grain is fed, the marrow becomes hyperplastic and packed with megaloblasts. That is, a state of the marrow comparable with that seen in pernicious anemia is induced. By adding liver to the diet the hyperplastic reaction was inhibited, the megaloblasts disappeared and the marrow assumed a normal appearance. Peabody also found that marrow removed during life from pernicious anemia patients, showed a reduction in the number of megaloblasts and a preponderance of normoblasts as a result of liver feeding.

The first detectable effect of specific treatment in pernicious anemia is a rise in the reticulocytes. In untreated cases of pernicious anemia these constitute 3 per cent or less of the red cells. In from 3 to 5 days after liver, a potent liver extract, or a gastric preparation has been given, large numbers of reticulocytes appear. The increase reaches its maximum about the fifth day, when the percentage is from 10 to 40 per cent. From then on the reticulocyte population declines, the immature cells having undergone maturation in the blood stream (fig. 22). This is reflected in an increased number of mature erythrocytes. The increase in the number of red cells, other things being equal, is proportional up to a point to the quantity of liver extract administered.⁴ When adequate amounts are given an increase to about the normal level occurs within 60 days. The lower the red cell count before treatment, the greater is the reticulocyte response to specific therapy. This fact is interpreted as indicating that in the more severe forms of the disease, megaloblasts constitute a large percentage of the marrow population; the anti-anemic principle hastens the development of these primitive forms to reticulocytes which are then promptly expelled into the circulation. When, on the other hand, the anemia is less severe the percentage of later forms, e.g., normoblasts in the marrow is greater and the stimulus to maturation exerted by the liver principle carries them to the adult stage. A larger proportion of mature eryth-

rocytes is therefore discharged into the circulation. In cases in which the red cell count is 3 million or over only a slight rise in the reticulocytes occurs, the rise in the red cell count being then due almost entirely to an increase in the number of mature cells.

The rise in the hemoglobin concentration of the blood lags behind the multiplication of the red cells so the color index returns to normal within a short time. If the stimulus to erythropoiesis is intense, the hemoglobin cannot be manufactured in sufficient quantities to furnish each cell with its quota of pigment and the color index falls well below the normal value.

FIG. 22. Showing effect of specific liver therapy upon the reticulocytes, erythrocytes, hemoglobin and plasma bilirubin (after Dyke).

With the improvement in the blood picture the general symptoms of the disease abate, but the secretion of acid gastric juice is very rarely restored. Liver treatment therefore does not remove the primary cause of the disease and its administration must be persisted in for the rest of the patient's life. The maintenance dose, is of course, much less than that required originally for the restoration of the normal blood picture. Cord changes which have occurred may be favorably affected if sufficient liver or liver extract is administered (p. 868). The nervous lesions are due, mainly at any rate, to a lack of the liver principle and not simply secondary to the anemia. Therefore, an amount of the liver principle which

⁴ The reticulocyte response of a pernicious anemia patient is usually employed in assaying the potency of liver preparations. No satisfactory animal assay method has been found.

TABLE 10
Summarizing chief hematological features of various types of anemia (see also figs. 19 and 20)

ANEMIA	ERYTHROCYTES	RETICULOCYTES	LEUCOCYTES	PLATELETS	BLOOD INDICES			FRAGILITY OF RED-CELLS	PLASMA BILIRUBIN AND PIGMENT EXCRETION
					Color	Volume	Saturation		
Hypochromic types due to iron deficiency	Moderately reduced Microcytes Poikilocytes	Normal or slightly increased			Marked reduction	Reduced	Marked reduction	Normal	Normal
Pernicious types	Greatly reduced Macrocytes Megaloblasts and normoblasts Poikilocytes	3 to 4 per cent	Reduced; with a shift to the right (p. 113) Relative lymphocytosis Leucocytosis in anemia of gastric carcinoma	Reduced	Raised	Raised	Raised	Reduced	Increased
Aplastic	Greatly reduced Primitive forms absent indicating a great reduction or a complete absence of the regenerating power of the marrow	Reduced or absent	Reduced Relative lymphocytosis Normal or reduced	Reduced	Normal or slightly reduced	Normal	Normal	Normal	Normal
Post-hemorrhagic: Acute	Reduced to variable degree Normoblasts Poikilocytes	3 to 10 per cent or so	Neutrophilic leucocytosis	Increased	Normal or moderately reduced	Normal or moderately reduced	Normal or moderately reduced	Normal	Normal
Chronic	Reduced Normoblasts Poikilocytes	Slight increase	Normal or slight reduction		Reduced	Reduced	Reduced	Normal	Normal
Acholic (hemolytic) jaundice	Reduced Normoblasts Poikilocytes Microcytes and polychromasia	5 to 60 per cent	Normal or moderate increase		Normal	Normal	Normal or raised	Greatly increased	Increased

In acholic jaundice it is only the diameter of the cell that is reduced; its thickness is increased so that the volume is about normal.

alleviates the anemia is not necessarily sufficient to arrest the neurological condition.

Macrocytic (hypochromic or hyperchromic) anemias with normoblastic bone marrow

Macrocytic anemias showing a resemblance to Addisonian anemia, in so far as the blood picture is concerned, occur in various diseases, e.g., gastric carcinoma, syphilis, hepatic cirrhosis, etc. But the bone marrow is of the normoblastic type. Since they are not due to deficiency of the anti-anemic principle, they do not respond to the administration of liver extract or of gastric tissue.

IDIOPATHIC APLASTIC ANEMIA

This is a comparatively rare type of anemia in which there is a rapidly progressive reduction in all the blood cells—erythrocytes, leucocytes and platelets. There is little or no evidence of blood regeneration, reticulocytes are very scarce and nucleated forms are usually absent. The red cell count may reach an extraordinarily low figure—213,000 per cubic millimeter in a case reported by Ehrlich. Granulocytes and platelets may entirely disappear. The marrow is hypoplastic or aplastic; there is a great reduction in its cellular elements and almost complete absence of hemopoietic activity. The lymphocytopenia which also occurs, but

is less marked than the reduction in granulocytes, suggests that the entire hemopoietic system is affected. The causes of the bone marrow hypoplasia have been mentioned (p. 62).

A number of cases have been reported recently (Thompson, Richter and Edsall; Anderson) in which the typical blood picture of aplastic anemia was associated with a normal or even a hyperplastic marrow. In these, to which the term "pseudo-aplastic anemia" might be applied, there would appear to be some interference with the maturation and delivery of the cells into the blood stream rather than to absolute suppression of marrow function.

It is only upon pernicious anemia or macrocytic anemias of the pernicious anemia type with a megaloblastic bone marrow that liver therapy has any specific effect. Other macrocytic types (with a normoblastic type of marrow), the microcytic anemias and aplastic anemia fail to respond to the administration of liver extract or to gastric tissue. In post-hemorrhagic anemia and certain other secondary anemias *whole liver* is of value, not from any specific action but simply because it furnishes iron and protein of high quality. The principal features of the blood picture in several types of anemia are summarized in table 10.

CHAPTER X

THE WHITE BLOOD CORPUSCLES OR LEUCOCYTES—THE PLATELETS

CLASSIFICATION AND MORPHOLOGY

The white blood cell differs from the erythrocyte in that it contains no hemoglobin, but has a well formed nucleus. The majority of the white cells are also considerably larger than the erythrocytes, measuring from 8 to 15 microns in diameter, the size depending upon the particular variety. They are much less numerous than the erythrocytes; in the adult they number from 5 to 9 thousand per cubic millimeter of blood. In infancy they are twice as numerous and throughout childhood the count is higher than in the adult. When a film of adult blood is examined under the microscope the white cells appear very sparsely scattered here and there among the crowds of colored corpuscles which outnumber them more than 600 to 1.

On a basis of morphological differences the colorless corpuscles are divided first into two main groups: (I) *Cells with a single nucleus and a clear nongranular cytoplasm*—the lymphocytes and the monocytes; (II) *cells having a lobed or incompletely partitioned nucleus, and a cytoplasm containing fine chromophil granules*—the *granulocytes*. Each of these two main classes are divided further into subgroups on a basis of differences in structure or staining properties¹ (see frontispiece).

I. THE NON-GRANULAR LEUCOCYTES— AGRANULOCYTES

These are of three varieties: (1) *Small lymphocyte*, (2) *large lymphocyte*, (3) *monocyte*. Though these forms show no granules in the protoplasm under the ordinary methods of staining, granulation may be demonstrated after staining with azure-blue. The lymphocytes contain a few coarse azurophil granules; those of the monocytes are fine and very numerous.

(1) **THE SMALL LYMPHOCYTES.** These are slightly larger than the red cells—about 8 microns in diameter. The nucleus is relatively large, slightly indented and stains more deeply with basic dyes than the surrounding narrow rim of cyto-

plasm which separates it from the boundary of the cell. The small lymphocytes originate in lymphoid tissue and are found in large numbers in the lymph nodes and spleen. They constitute in the adult from 20 to 25 per cent of the total number of white cells in blood and are the commonest cells found in lymph. In childhood lymphoid tissue is much more abundant than in adult life and the lymphocytes are more numerous. They amount to from 50 per cent or more of the leucocytes in early childhood and to about 35 per cent at the age of ten years.

(2) **LARGE LYMPHOCYTES.** These resemble the preceding in general appearance but are considerably larger, being 12 or more microns in diameter. The cytoplasm forms a wider zone about the nucleus, which is oval or kidney shaped. These cells are found in insignificant numbers in adult blood but are more plentiful in the blood of young children. They are practically confined under physiological conditions to the lymphoid tissue, but even here they are greatly outnumbered by the small lymphocytes. They are considered by many as a younger form of the small lymphocyte.

(3) **THE MONOCYTES** are from 10 to 15 microns in diameter. They possess a relatively larger amount of cytoplasm. The nucleus has a deep indentation on one side, which gives it a kidney or saddle-bag shape. On the supposition that this cell represented a stage in the development of the polymorphonuclear leucocyte, it was called the "transitional leucocyte" by Ehrlich. This view has since been shown to be wrong, for the monocyte bears a relationship to the lymphocytes rather than to the polymorphonuclears. It has been mentioned that the monocyte contains, like the lymphocytes, azurophil granules in the cytoplasm. The monocytes are actively motile and phagocytic, and are considered by most observers to be derived from fixed histiocytes (p. 80). Such an origin would class them as circulating elements of the reticulo-endothelial system. According to Maximow, however, they arise from lymphocytes. They constitute from 5 to 6 per cent of the white cells.

Small numbers (0.2 per cent) of a slightly different type of monocyte are also found in blood. Its nucleus instead of being kidney-shaped is round or oval. It

¹ The term leucocyte is employed by most authors to denote all the white cells, and this from the simple meaning of the word seems logical. Some, however, confine the term to the granulocytes. The first of these usages will be followed in this text.

was previously known as the large mononuclear leucocyte, but it is probably simply a younger form of the preceding variety.

II. THE GRANULOCYTES

These are divided into three groups according to the staining reactions of their granules. One type—the *eosinophilic*—stains with acid dyes, e.g., eosin; another—the *basophilic*—stains with basic dyes, e.g., methylene blue; and the third type—the *neutrophilic*—with neutral dyes, i.e., mixtures of acid and basic dyes. These staining reactions apply to human leucocytes, but such distinctions cannot always be made in other animal species. The nucleus of a granulocyte is composed of two or more lobes connected together by strands of chromatin.

(1) The **EOSINOPHILS** are not numerous; they amount to no more than 3 or 4 per cent of the total white cell count. The granules which are oval and much coarser than those in the other two varieties are stained a bright red with eosin. The cell is also slightly larger and the nucleus usually bilobed. In certain pathological conditions which will be mentioned later they may form a much larger percentage of the leucocyte population.

(2) The **BASOPHILS** are present to the extent of only 0.5 per cent or less. Their granules stain deeply with methylene blue. Their significance is not known. They have been considered by some observers to be degenerated neutrophils, but there appears to be little doubt that they are a distinct type and like the other granulocytes a product of the bone-marrow. Support is lent to the latter view by the fact that they are increased in conditions associated with excessive marrow activity, e.g., chronic myelocytic leukaemia and polycythemia vera. They are also increased in chronic inflammation of the accessory nasal sinuses.

(3) The **NEUTROPHILS** are by far the most numerous, constituting from 65 to 70 per cent or more of the total number of white cells. Their granules are quite small and are stained a violet tint with neutral dyes. As will be seen presently the neutrophils are actively ameboid in character, i.e., they are capable of locomotion and ingest foreign particulate matter. They are about 10 or 12 microns in diameter.

The Arneth count or index

It was pointed out by Arneth that the number of lobes in any neutrophil depends upon the cell's age, the older cells having the larger number. A five-lobed nucleus for instance indicates a stage in the life of a cell

just preceding its final dissolution; an unlobed but deeply indented nucleus, a very young cell. Five stages in the life history of the polymorphonuclear leucocyte are therefore distinguished corresponding to the number of lobes developed in the nucleus. A count of the nuclear partitions in the cells of a blood film will give the proportion of cells of different relative ages. In figure 23, stage I shows a nucleus with a single lobe. Constriction of the nucleus can be seen but the nuclear substance is continuous from one part to the other. In stage II the nucleus is partitioned into two parts which are connected only by chromatin threads. In the next stage 3 lobes are seen and so on to the last or senile stage in which the nucleus has 5 or more lobes. These latter are large edematous non-motile cells with non-staining granules. In some conditions, e.g., acute septic infections and pernicious anemia, very large cells (up to 20μ) with a great number of nuclei are seen. These are known as *macropolycytes*.

The Arneth index is determined by counting the number of nuclear lobes in each of 100 neutrophils. The cells in the different stages are expressed as percentages of the total. The count under the ordinary conditions of health is as follows:

	Percentage of leucocytes
Stage I.....	5
Stage II.....	30
Stage III.....	45
Stage IV.....	18
Stage V.....	2

In certain diseases the youngest cells (Stage I) are much more numerous and may constitute 50 per cent of the total. There may be an entire absence of cells in the later stages (IV and V). An increase in the percentage of cells of the earlier stages is spoken of as a "shift to the left." It is seen in conditions which stimulate the bone marrow to a greater production of white cells, e.g., pyogenic infections. It is also seen in tuberculosis and after exposure to the X-rays and after the injection of thyroid extract. In children a shift to the left occurs much more readily than in adults. In pernicious anemia the percentages of the older cells increase—"shift to the right"—and in some cases, as mentioned above, macropolycytes appear. Except in the case of the senile non-motile cells a relationship between the phagocytic activity of a particular cell and its age has not been demonstrated.

The *Schilling index* employs a simpler classification of the neutrophils. Four stages are recognized (a) the myelocyte which shows a single spherical nucleus; (b) young metamyelocyte with a slight indentation of the nucleus; (c) older metamyelocytes with the process of lobulation definitely indicated; this is known as the band cell of Schilling or "Staff" cell and corresponds to the first stage of Arneth; (d) older neutrophils, i.e., the other stages of Arneth. Stages (a) and (b) are not

found normally in the blood. They appear when a pronounced "shift to the left" occurs. (See frontispiece and p. 85.)

The non-motile cells of the last or fifth stage of Arneth appear, periodically in increased numbers—in "showers"—in the blood stream. They are replaced by young cells from the marrow. Like

FIG. 23. Arneth stages (after Cook).

FIG. 24. Sketches of a neutrophil at time intervals of a few seconds.

the red cell the dying neutrophils disintegrate in the circulation or are disposed of by the macrophages of the spleen or the tissues. The life span of the neutrophils has been variously estimated. By some it is believed to be no more than about 3 days and by others no more than a few hours. Ponder, however, puts it at 21 days. He induced a leucocytosis and shift to the left in the Arneth stages by the injection of thyroid extract and fol-

lowed the blood picture until the polynuclear count returned to normal. Since the rise in the count is due to the discharge of young cells (Stage I) from the marrow, when the count again showed the normal percentage of cells of State V it was assumed that the discharged cells had reached the end of their life-span. At any rate the average life of the neutrophils is apparently much shorter than that of the red cell (p. 57).

THE FUNCTIONS OF THE LEUCOCYTES

The neutrophilic polymorphonuclear leucocytes as well as the monocytes and other reticulo-endothelial elements constitute probably the most important elements which the body possesses for its defense against invading microorganisms. Their power to attack bacteria depends upon their motility and a proclivity for the ingestion of solid particles. The latter action which was first demonstrated by Metchnikoff is termed *phagocytosis* (phago—I eat). These two varieties of white blood cell are free lances among the body cells; they wander from place to place through the tissues and practically no part of the body is barred to them. They insinuate a process (*pseudopodium*), improvised at the moment from their cell protoplasm, through one of the joints in the endothelium of the capillary wall. Then by causing the semi-fluid substance of the cell-body to stream into the protoplasmic projection, they pass out of the blood vessels at will. By this action of *diapedesis*,² as it is called, myriads of white corpuscles may pass out of the vessels in a remarkably short time. Reaching a point where the bacteria have entered the body they surround the threatened area and proceed to destroy the invaders. If, for instance, an actively inflamed region should be examined under the microscope, masses of neutrophils would be seen, and many of these would be observed to hold bacteria imprisoned within their bodies. As many as 15 or 20 organisms may be seen at times within a single cell. It has been shown that the germs are ingested alive and remain so for a time within the leucocyte.

When a tissue such as the mesentery or web of a frog, in which the capillaries are clearly visible, is examined in the living state a short time after a culture of bacteria has been injected into it, the small vessels leading to the site of inoculation are found swarming

² The term diapedesis, literally a "leaping through," is sometimes applied to the passage of red cells through an unbroken capillary wall, but the term is scarcely appropriate for a passive process of this nature.

with neutrophils. In the tissues round about, the ameboid cells are seen moving somewhat ponderously hither and thither to engulf the offending bacteria. When the latter are intensely virulent in nature this normal leucocyte reaction may be seriously depressed. The monocytes, though much less numerous, also join in the general attack and show their phagocytic propensities to a marked degree. After the first flooding of the tissues with neutrophils and monocytes, numbers of the latter come to rest and together with other reticulo-endothelial elements of the tissues undergo transformation and aid in isolating the infected area from the neighboring healthy tissues. Until this is accomplished the danger of the infection becoming more wide-spread always exists. In their struggle against bacteria, equipped as these are with powerful toxins, many of the white cells are killed. These collect within the center of the area together with exuded plasma, liquefied tissue cells and a few red cells that have escaped through the injured walls of the capillaries. This material constitutes pus, and the so-called pus-cells are dead leucocytes. The circumscribing wall and its semi-fluid contents constitute an abscess. By the action of the phagocytes, aided by a protein digesting ferment (protease) which they elaborate, the overlying structures whether connective tissue, mucosa or skin are in part removed piecemeal. In this way a communication with the exterior is effected and the contents of the cavity are discharged.

Not only bacteria but practically any foreign material, whether a rose-thorn or a catgut suture is attacked and removed if possible, or loosened by the neutrophils aided by the monocytes and other phagocytic cells of the tissues. The removal of dead tissue or of blood clot or the separation of necrotic from living structures is accomplished in the same way. Devitalized bone though not removed in its entirety, unless it be of very small size is nevertheless eroded and separated from the living tissue by the leucocytes. The disappearance of effete organs such as the tail and gills of the metamorphosing tad-pole or the creeping muscles of insect larvae, as these develop to the mature form, is effected by similar phagocytic cells. The application of heat to a part also attracts leucocytes in large numbers to the capillaries from which they immediately commence to migrate.

The activity of the leucocytes is best studied by the method of Clarke, in which a transparent chamber is inserted into the tissues, e.g., the rabbit's ear. After a time fine vessels grow into the chamber through openings in its sides which may be examined under the microscope. Another very simple method is that of *supravital staining*. A thin film of a non-toxic (supravital) dye, e.g., neutral red, azure, brilliant cresyl blue, is laid upon a glass slide and allowed to dry; a film of blood is laid over this and covered with an ordinary cover glass which is then sealed with vaseline around the edges. The preparation is kept warm and examined under the microscope, the cells remaining alive

and active. The neutrophils seen in such preparations are not round as in fixed smears, but are continually changing their shape. Pseudopodia are in constant movement and the granules can be seen streaming through the cytoplasm with each movement of the cell. The rate of progression of the neutrophil is from 30 to 35 microns per minute at body temperature (fig. 24).

Oxidase reaction. When granulocytes are subjected to the following technique brownish black granules appear in the cytoplasm. Equal parts of a 2 per cent solution of beta-naphthol sodium and a 1 per cent solution of dimethyl-paraphenylene-diamine hydrochloride are mixed, and the mixture filtered. An air-dried blood film is treated with the filtrate. Lymphocytes or monocytes do not give the reaction, which depends upon the presence of specific granules. At the earliest stage in the development of the granulocyte (stage of the myeloblast, p. 84) the reaction is also negative, is ill defined in the next older stage (myelocyte A), but well marked in the more mature forms.

The functions of the other varieties of granulocytes—the eosinophils and basophils—are unknown. The eosinophils are not markedly motile and only slightly phagocytic. Also little is known of the functions of the lymphocytes. A great migration of lymphocytes characterizes certain chronic types of inflammation. By being transformed into fixed connective tissue elements (fibroblasts) they are thought to aid in repair processes. They are not ameboid, that is, they do not progress by the protrusion of pseudopodia. But they are capable of a certain slow progression, as a result of spasmodic movements of the cell-nucleus. The lymphocytes have little phagocytic power and from all accounts possess no proteolytic ferment. They are constantly being shed from the mucous surfaces of the body in enormous numbers, and it has been suggested that they furnish antibodies or in some way serve to adsorb or inactivate toxins, and so contribute toward the body's defenses.

The work of Murphy and others suggests that the small lymphocytes are important elements in the resistance of animals to tuberculosis and to cancer. Tumor tissue or even healthy tissue when transplanted from one animal to another is followed by a great increase in the lymphocytes of the blood and in the tissues in the neighborhood of the graft. Hard X-rays have a selectively destructive action upon lymphoid tissue, and when animals were exposed to the rays the lymphocytic reaction to the grafted cells was suppressed; the animal's susceptibility to the tumor growth was increased. Single small doses of soft X-rays, however, have a stimulating effect upon lymphoid tissue and the production of lymphocytes; animals exposed to these rays showed a marked increase in the

number of lymphocytes in the region of the growth (round-cell infiltration) and their resistance to the graft was increased. Dry heat caused a similar stimulating effect and a corresponding rise in resistance. These blood-cells may also be increased 100 per cent by the injection of foreign protein. The susceptibility of animals to experimental tuberculosis was also shown to be reduced by measures which stimulated lymphocyte reactions.

Trophones. Carrel found that though epithelial cells and fibroblasts could be cultured outside the body in embryonic juice, for the continued growth of these cells in adult plasma the presence of lymphocytes was essential. The lymphocytes elaborate substances from nitrogen compounds (proteins) of the serum upon which the growing cells feed. These nutritive materials or *trophones*, as Carrel calls them, are also produced by the leucocytes in vivo and must constitute an important factor in tissue repair and tissue growth.

VARIATIONS IN THE NUMBER OF LEUCOCYTES IN THE BLOOD STREAM

LEUCOCYTOSIS

In the event of some damage to the tissues which calls forth a leucocytic response, not only is there a migration of leucocytes from the blood to the site of injury, but also a discharge of these cells from the marrow and an increase of their number in the general circulation. Instead of the normal count of seven or eight thousand per cubic millimeters the colorless cells may number 20 to 30 thousand within a short time. *Leucocytosis* is the term used to designate an increase in the total number of white cells. All varieties of the white cells do not necessarily share in the increase. In one instance it may be the neutrophils, in another the lymphocytes or the eosinophils that are increased, and it is the presence in abnormal numbers of one or other of these which then gives the high total leucocyte count. It is often of great diagnostic value to know which type of cell is responsible for the leucocytosis, and in order to determine this a so-called *differential count* of the cells is made. That is, the numbers of the different types in a stained smear of blood are counted and their percentages of the total count are determined. Also, changes in the proportions of the different white cell types may occur though their total number be normal. Such alterations can be revealed only by a differential count. The following example is given in illustration; the lymphocytes and monocytes are relatively increased; the neutrophils and eosinophils reduced.

Total white cells per cubic millimeter.....	75
Lymphocytes, per cent.....	
Monocytes, per cent.....	
Neutrophils, per cent.....	
Eosinophils, per cent.....	

Very commonly an increase in the neutrophils is entirely responsible for the leucocytosis. On account the latter term is used frequently somewhat loosely to imply an increase in count caused by the neutrophilic elements alone. *Neutrophilia* is a more precise term that is coming into use for the latter condition. *Lymphocytosis* and *eosinophilia* are the respective terms employed to designate increase in the other elements.

Acute infections by the pus-forming organisms, staphylococcus, streptococcus, etc., are the most potent causes of a neutrophilic increase. On account the examination of the white cells furnishes a valuable diagnostic sign for the detection of hidden inflammatory conditions, e.g., appendicitis, empyema, etc. A neutrophilic leucocytosis occurs also in pneumonia, whooping cough, scarlet fever, and some other infectious fevers. The nucleated count shows an increase in the young stages at the expense of the older (p. 72).

Chemotaxis is the term applied to the unknown "force" which draws the white cells from their storage houses into the blood stream and from here to the point of injury in the tissues. It was formerly thought that the chemical properties of the bacterial toxin were responsible for this effect, but it has since been shown that nucleic acid and its derivatives (guanine, adenine, adenosine, etc.) are the specific stimulants. Injections of these substances cause a rapid rise in the leucocyte count. Toxins or other injurious agents act probably indirectly by liberating nucleic acid from the tissue cells as well as from injured leucocytes themselves. It has been suggested that the actual force which attracts the cells from the vessels to the tissue focus may have changes in surface tension of the blood cell membrane as its basis, for during the early stages of the inflammatory reaction the leucocytes in the small vessels near the injured site appear "sticky." They collect and cling to the walls of the vessels and are thus separated from the red cells which occupy the axis of the stream. Experiments, however, upon unicellular organisms such as the amoeba to which the white cell bears a strong resemblance have failed to show that the spontaneous movements are surface tension phenomena. It must be admitted that the chemotactic effect still remains a problem to be solved. It has been suggested that the attractive force is electrical rather than chemical in nature, a potential difference being set up between the injured (relatively negative) and

thy tissue, the leucocytes exhibiting the phenomenon of *galvanotropism*. Menken has obtained a crystalline nitrogenous material from inflamed tissues which he states causes increased capillary permeability and the migration of leucocytes through the endothelial wall. He calls this substance *leukotaxine*. On the other hand the expulsion of the crowds of leucocytes from the bone marrow is more probably a vaso-motor action, involving the communication with the general circulation of capillary sinuses filled with cells. There is evidence that capillary sinuses loaded with cells and previously closed from the general circulation are suddenly opened to allow their contents to be swept into the blood stream. This is indicated by the fact, among others, that even the intravenous injection into a rabbit of 1 cc. of saline causes about 300,000,000 mature neutrophils to enter the circulation within an hour.

Physiological leucocytoses. It had formerly been thought that an increase in the neutrophils occurred during digestion—*digestive leucocytosis*—but it seems that this was a misconception. These cells show spontaneous rhythmical variations in their numbers, the total white cell count reaching its maximum of about 10,000 to 8000 in the afternoon, and its minimum, 5000 to 6000 in the early morning. These variations occur quite independently of meals. Leucocytosis also occurs during pregnancy, parturition and menstruation, after muscular exercise and after adrenaline administration, or in states such as fear, pain, anoxia, etc., which cause the liberation of adrenaline from the adrenal gland. In infants and young children the leucocyte count is considerably higher than in adults; the count is also less constant in infancy, varying without apparent cause by two thousand or more per cubic millimeter.

Eosinophilia, or increase in the number of circulating eosinophils, occurs in several conditions, notably allergic states, e.g., certain skin diseases, asthma and anaphylactic shock, and in infections by various animal parasites, e.g., *hook-worm (ankylostoma duodenale)* disease, in which the eosinophils may be 30 per cent of the total white cell count, and in *trichiniasis*. In the latter infection there is a general leucocytosis, with the eosinophils running as high as 50 per cent or more per cu. mm. Infections with hydatids, ascaris and other worms also cause eosinophilia to a greater or less degree. The significance of this association of eosinophilia with parasitic infection is unknown. During the acute stage of pyogenic infections the eosinophils are reduced in number (*eosinopenia*); in the convalescent stage they are increased.

Lymphocytosis. The neutrophils are not stimulated by tuberculous, malarial, or syphilitic infection. In the active stage of such conditions either an absolute or relative increase in the number of circulating lymphocytes is the rule. In other chronic inflammatory states and in infections with the colon or diphtheria bacillus also, it is the lymphocytes rather than the neutrophils that are increased in number. They indicate in general

an inflammatory condition that is undergoing repair is being held in check, or at the most is making slow progress. Lymphocytosis, therefore occurs as an aftermath of acute infections. The neutrophils on the other hand represent the "shock troops" and their presence indicates that a more active campaign is being waged. In young children a relative lymphocytosis is the rule.

Monocytosis occurs in glandular fever, a condition associated with a general enlargement of the lymph glands. The monocyte count may be 15,000 or 20,000 per cubic millimeter. The monocytes are also increased in pulmonary tuberculosis. According to Cunningham a decline in the lymphocyte count and an increase in the monocytes in this condition indicates that the process is being arrested. Monocytosis also occurs in malaria and in syphilis.

The leucocytic responses in the conditions considered in the foregoing paragraphs are "purposeful." That is, they are normal protective reactions. In the blood disease known as *leukemia*, however, an enormous increase in the number of leucocytes is a primary feature and essentially pathological. The white cell count may be 500,000 or more per cubic millimeter. It is a disease that affects the maturation and multiplication of the white cells with the appearance of abnormal forms in the blood stream (p. 85).

LEUCOPENIA

Leucopenia means a reduction in the number of circulating leucocytes. It is seen in certain diseases, notably typhoid fever, and may be induced experimentally by injections of the toxin of the typhoid bacillus—or emulsions of the dead organisms. In some cases in which the white cells are reduced in number in the blood, the reduction is due to their attraction to some solid organ such as the lung or spleen. This has been shown by taking blood counts from various regions. In other words leucopenia may be due to a redistribution of leucocytes in the body, rather than to an actual reduction in their number. A temporary fall in the leucocyte count may precede a leucocytosis. Certain poisons, e.g., benzol, cause leucopenia by depressing the activity of the bone marrow (see also p. 69).

Granulocytopenia, agranulocytosis, etc. *Granulocytopenia* is the term applied to an abnormally low leucocyte count due to the reduction in granulocytes. The lymphocytes and monocytes are but slightly reduced or not at all, so that their proportion of the total count is increased. There may be complete absence of granulocytes when the term *agranulocytosis* is applicable. In

most instances the absence of granulocytes is associated with a severe septic or necrotic condition of the throat. This condition, called *agranulocytic angina*, is fatal in the great majority of cases. The cause of these conditions is unknown but the fault is evidently one of the bone marrow, and is probably induced by some toxic agent. The marrow shows, frequently, an almost complete suppression of granulocyte formation but is normal so far as erythropoiesis is concerned. In animals reduction in the granulocytes is readily induced by the administration of benzol which acts specifically to depress marrow activity and there is a belief that in some cases agranulocytosis is induced by certain benzol derivatives employed for their antipyretic or analgesic properties. The arsenobenzenes, dinitrophenol and, though rarely, sulphanilamide and sulfathiazole have been incriminated. Amidopyrine is a drug which has been most strongly suspected in this connection. In the treatment of these conditions, pentose nucleotide is employed with the object of stimulating the granulopoietic functions of the marrow.

In some cases of agranulocytosis there is also a marked reduction in lymphocytes and bone marrow shows an increase in the number of primitive cells of the granulocyte series (myelocytes and myeloblasts). The maturation of granulocytes is apparently arrested at an early stage, (p. 84). From the analogy between this fault in granulopoiesis and the erythropoietic abnormality seen in pernicious anemia, the condition has been termed *pernicious leucopenia*.

THE BLOOD PLATELETS (THROMBOCYTES)

These are commonly stated to be simply fragments of protoplasm (i.e., non-nucleated) derived from the cytoplasm of the megakaryocytes (p. 85). Their colorless cytoplasm contains two types of granules. Those of one type are arranged in clumps or chains and stain supravitaly with neutral red. The other type are discrete and stain supravitaly with Janus green. The platelets have an average diameter about a third that of a red cell, namely, 2.5 microns, and number from 200,000 to 400,000 per cubic millimeter. They vary considerably in shape. Their best known function is concerned with the mechanism of blood-clotting (p. 88), since they are believed to liberate throm-

bokinase when they disintegrate. The disintegration of the platelets is said to occur more readily in blood drawn during the digestion of a meal of meat.

Variations in the number of platelets occur in the following conditions. They are *increased* after a meal of meat, after hemorrhage, and in certain allergic conditions, in myeloid leukemia and in convalescence from infections.

They are *diminished* in purpura hemorrhagica, aplastic anemia, pernicious anemia, in anaphylaxis and in the acute stage of septic infections.

The number of platelets per cubic millimeter is determined most conveniently by diluting a sample of blood with a fluid composed of sodium citrate 3.8 per cent, formalin 0.2 per cent and brilliant cresyl blue 0.1 per cent, and counting immediately. The proportion of platelets to red cells (normally about 1 to 20) is determined. If the number of red cells per cubic millimeter be known then the corresponding number of platelets is readily calculated.

Besides their well-known rôle in the coagulation of blood (p. 88) the platelets probably serve other functions. They have a pronounced tendency to agglutinate into masses and to form deposits upon any roughened surface or foreign material. Particles of India ink or microorganisms injected into the body become surrounded by a mass of agglutinated platelets. They may therefore aid in the body's defense against infective organisms. It is probable also that they serve to seal leaks in the capillaries by adhering to small defects which may occur from time to time in the delicate endothelial wall. They constitute the first defense against the loss of blood from larger vessels. Collecting around the margins of the vascular wound they help to close it, or at any rate serve to fasten the clot, which subsequently forms, to the vascular wall, and, through their action in inducing retraction and consolidation of the clot, to narrow the opening in the vessel and form a firm plug within its lumen.

CHAPTER XI

THE ORIGIN OF THE BLOOD CELLS

INTRODUCTION

There are two main schools of thought concerning the development of the blood cells in postnatal life. (a) The *unitarian* or *monophyletic* school holds the view that all types of blood cell are derived from a common primitive free cell which they term the "*stem cell*" or *hemocytoblast*. (b) The *dualistic* school believes in the existence of two distinct types of stem cell, one in the bone marrow which gives rise to the myeloid elements—erythrocytes, granulocytes and megakaryocytes, and the other in lymphoid tissue which is responsible solely for the genesis of the lymphocyte. It is not possible to speak unreservedly for either theory though the unitarian view seems to have the balance of evidence in its favor and will be followed in this text. Both schools are agreed, however, that in the early embryo the mesenchyme gives rise to a primitive free cell from which all the blood cells are derived. It is also generally conceded that certain cells of the bone-marrow and lymphoid tissues of the adult (p. 78) are the representatives of the mesenchyme cells of the embryo and to such cells all the blood cells trace their lineage.

The point at issue is, "Do the bone-marrow and lymphoid tissues give rise to two cell types, with their potentialities restricted, the one to the development of myeloid elements, the other to the development of lymphocytes?" Or, "Do both types of tissue give rise to a primitive free cell—the stem cell or hemocytoblast—with potentialities for the production of all types of blood cells, but whose development along one or other line is determined simply by its immediate environment?" The latter is the monophyletic view (Pappenheim, Maximow).

It is not maintained, however, that the individual blood cells arise, under ordinary circumstances, in direct line of development from the stem cells, that is, each blood cell from a hemocytoblast. In health, the blood cells are produced through the multiplication of cells belonging to later stages of hemopoiesis (erythroblasts and myelocytes, p. 83 and p. 85). In other words a single stem cell is the ancestor of many millions of mature blood cells. This type of development, involving the proliferation of cells of later stages

and the production of daughter cells of the same type which then undergo maturation, is called *homoplastic hemopoiesis*.

Under pathological conditions, on the other hand, the stem cells may undergo active proliferation, and produce, directly, immature blood cells (erythroblasts of various ages, myeloblasts and myelocytes). This is termed *heteroplastic hemopoiesis*.

The schemata shown below will enable the reader to follow the description of the blood cell origins which will now be given.

HEMOPOIESIS (BLOOD FORMATION) AT DIFFERENT EMBRYONIC AGES IN THE EARLY EMBRYO

The yolk sac. The first signs of blood and blood vessels appear in the mesenchyme of the wall of the yolk sac, i.e., outside the embryonic area proper. At a very early stage groups of mesenchyme cells in this situation—the *blood islands of Pander*—are first observed to arrange themselves into cords or columns which soon separate into a central and two outer layers.

The outer two enclosing layers form the walls of the primitive blood vessel—*primitive endothelium*. Of the central group some go to form the first blood cells, while the secretion or actual solution of others forms the *plasma* in which the cells are floated. These free floating elements are known as the *primitive blood cells*. After this the mesenchyme loses its power to produce blood cells directly. A few primitive blood cells may arise from the primitive endothelium from time to time but they are few in number and the process is believed to be relatively unimportant in most mammals, and does not persist for long. The further development of the primitive blood cells follows one or other of two courses. (a) Some of the cells—*primary erythroblasts* and *erythrocytes*—acquire hemoglobin and serve as oxygen carriers. These are short lived and soon disappear forever. (b) The rest remain colorless and apparently unchanged from their primitive state; *they are very similar to, if not identical with, the large lymphocyte*. These cells are found in adult bone marrow and lymphoid tissue, and in small numbers in circulating blood. They are termed by Maximow "*hemocytoblasts*" and upon them the monophyletic conception of blood formation in post-embryonic life is based. They are the "*stem cells*" and are, according to the unitarians, potentially capable of producing any of the blood cells in the adult. Though these cells are identical, morphologically, with the primitive blood cells of which they are an older stage, apparently they are functionally

different, for they form *secondary* erythroblasts and erythrocytes (which the primitive cells do not) but never *primary* erythrocytes (see chart, p. 79). They also give rise to megakaryocytes. The latter are enormous cells (40 μ) with multi-lobed nuclei. The primitive endothelium as well as the primitive blood cells gives rise to hemocytoblasts and also to a few histiocytes (p. 80) which show phagocytic proclivities, devouring degenerated red cells. In mammals few granulocytes are formed within the yolk vessels. They arise extravascularly from hemocytoblasts derived from the mesenchyme cells.

IN THE BODY OF THE EMBRYO. While these stages of blood-development are proceeding in the mesenchyme of the yolk-sac, the heart and vessels are developing in the embryonic area. Soon the embryonic and extra-embryonic systems of vessels form communications with one another and the primitive blood-plasma, primary erythrocytes and hemocytoblasts flow into the body of the embryo. The mesenchyme cells of the general connective tissues of the embryo's body also form hemocytoblasts at this time. From these stem cells secondary erythrocytes and later, granulocytes and lymphocytes are produced. Blood formation throughout the general mesenchyme is, however, of short duration. Hemopoiesis soon becomes localized in the liver, spleen, bone marrow and lymph glands. Normally it is only in these situations that the mesenchyme cells exhibit their powers of producing hemocytoblasts; therefore, it is exclusively in these tissues that the hemopoietic function for a time is carried on.

IN LATE EMBRYONIC AND POST-NATAL LIFE

In the later part of pre-natal life of most animals, the liver and spleen (except the lymphoid tissue of the latter) lose the power to produce stem cells and so, no longer serve as blood forming organs. The hemopoietic function from now on resides solely in the bone marrow and lymphoid tissues (p. 82). The marrow is concerned with the production of red cells, granulocytes and platelets; the lymphoid tissue of lymph glands, of the Peyer's patches of the intestine, and of the spleen and thymus form lymphocytes. In certain animals, such as the opossum and frog, the formation of red cells (erythropoiesis) and of granulocytes (granulopoiesis) is continued throughout adult life by the spleen. In the bird though the marrow is the chief organ for blood formation the liver still retains in part its embryonic hemopoietic function.

In late embryonic and post-natal life the mesenchyme gives rise to three main types of cells.

(a) Those which retain their embryonic potencies throughout adult life, being capable of producing hemocytoblasts (stem cells) and so of generating any of all of the blood cells. Some of these, called the

embryonic reticular cells, are situated in the reticulum of the bone-marrow and of the lymphoid tissue. Ordinarily these cells, as stated on page 77, are restricted in their hemopoietic activities, the great majority of the blood cells in conditions of health being formed by the divisions and re-divisions of cells of their own kind (homoplastic hemopoiesis). Cells having similar potencies are also present in the general connective tissues, and in these situations are spoken of as *undifferentiated mesenchyme cells*. Under ordinary circumstances these latter cells do not give rise to stem cells. As the result of some abnormal stimulus, however, their dormant powers inherited from their mesenchyme ancestry may become aroused and they may then give rise to the various types of blood cells. For example, areas resembling marrow tissue may be produced by the experimental stimulation of these undifferentiated cells; the several types of blood cells are formed within such areas. Maximow rendered the kidney of the rabbit necrotic by tying the renal vessels, and thereby induced in this situation hemopoietic activity resembling that which occurs in adult red-marrow. Marrow-like tissue producing erythrocytes and granulocytes may also arise as a result of an abnormal stimulus, in the spleen, liver, adrenals, aorta, lymph nodes and other sites. In certain forms of anemia, especially of infants, the extra-medullary formation of red cells sometimes occurs (in kidney, spleen, liver, etc.) and in leukemia, granulocytes, which normally arise only in the bone marrow, are produced by the spleen.

(b) The second type of cell has retained a certain measure of its embryonic characteristics. These cells are endowed with the remarkable power of altering their form and functions under appropriate stimulation. They are found in the general connective tissues lying among the fibroblasts. They are allied to the connective tissues on the one hand and on the other to certain white cells (monocytes) of the blood and so form a connecting link between the tissues and the circulating cells.

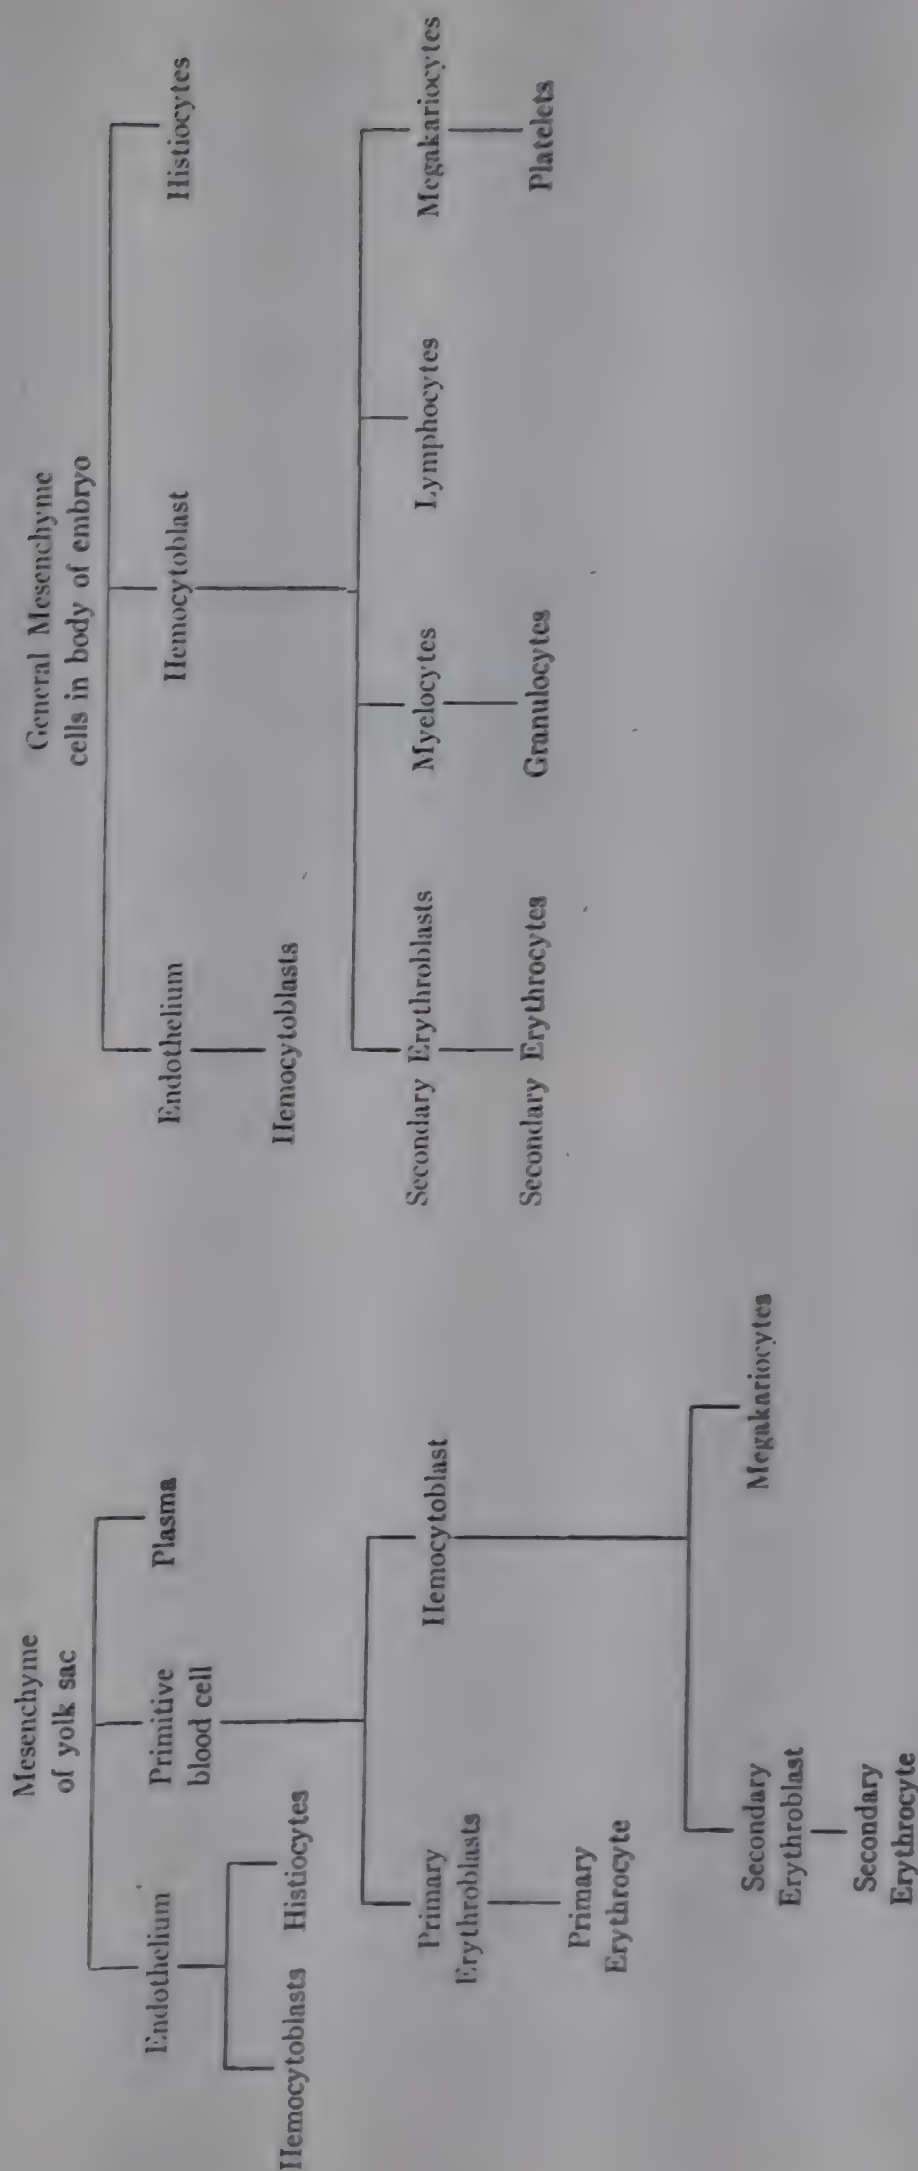

The cells of this group constitute what has been termed by Aschoff the *reticulo-endothelial system* (see below).

(c) In the general connective tissues the great majority of the original mesenchyme cells become transformed into the ordinary and completely differentiated connective tissue elements—the fibroblasts. These, once formed, remain practically unchanged in structure and in function.

THE RETICULO-ENDOTHELIAL SYSTEM

To the cells of this system the general term *histiocyte* has been applied. The term simply means a tissue-cell, and on this account is without descriptive value. But it would be difficult to coin a word that would embrace all the various cell-types of this system, and yet would be sufficiently explicit to distinguish them from some of

Diagram to show the development of the blood cells in the early embryo

the blood cells. *Pyrrol* cells is a term that has been used in the past for a reason that will appear presently. The different types of histiocytes possess one characteristic in common. They are phagocytic for foreign particles of all sorts; and for this reason they were called *macrophages* by Metchnikoff to distinguish them from the much smaller phagocytes of the blood—the neutrophils or *microphages*. In one particular, however, the histiocytes differ from all other cells of the body—neutrophils included. They are stained in the

VARIETIES OF RETICULO-ENDOTHELIAL (R.E.) CELL

The reticulo-endothelial cells or histiocytes may be divided for the convenience of description into two groups—*fixed* and *wandering*. (Cf. chap. p. 81.)

I. Fixed R.E. cells

(1) OF THE COMMON CONNECTIVE TISSUES (TISSUE HISTIOCYTES) and of the loose tissue of the serous membranes, e.g., omentum, pleura, etc. These are also sometimes referred to as “resting wandering cells.”

FIG. 25. Liver from an animal after the intravenous injection of India ink. K, Kupffer cells loaded with ink particles; L, liver cells.

FIG. 26. A, macrophage loaded with particles of India ink; B, macrophage showing processes. C, red cell.

living state by weak solutions of certain colloidal dyes—pyrrol-blue, trypan blue, lithium carmine, etc. The vital or supravital staining reaction is simply a process of ultramicroscopic phagocytosis. That is, the fine ultramicroscopic particles of the dye are taken up from the solution (which is too dilute to stain ordinary cells) and as a result of their accumulation into larger masses in the cytoplasm become visible under the microscope. It is by means of this reaction that the macrophages are able to be detected among the ordinary tissue cells from which it is sometimes otherwise difficult to distinguish them.

Their morphological characteristics are various. Some are round or spindle-shaped, others are squamous, while many have long mobile processes. They lie among the fibroblastic elements and often can be distinguished only with difficulty from the latter except by their special staining reactions. They may at any time as a result of some stimulus, particularly one of an inflammatory nature, become free and wander through the tissues. After the stimulus has been removed they may again come to rest.

(2) OF THE RETICULUM of the spleen, lymph glands, and bone marrow. These are large cells joined to one another by means of long branching processes. They lie among, and are attached to, the fibers of the reticular stroma. They too, given the necessary stimulus, may become detached and actively motile.

(3) FLAT ENDOTHELIAL-LIKE CELLS lining the blood sinuses of the spleen, bone marrow, adrenal cortex and pituitary. This group also includes those most interesting structures—the large flattened stellate cells in the blood sinuses of the liver (Kupffer cells). The latter possess many branching processes and project into the capillary lumen. In many instances they are almost free, being moored to the capillary wall by a delicate strand of protoplasm. At other times they may become quite free to be carried away in the blood stream (fig. 25).

(4) MICROGLIA of the central nervous system.

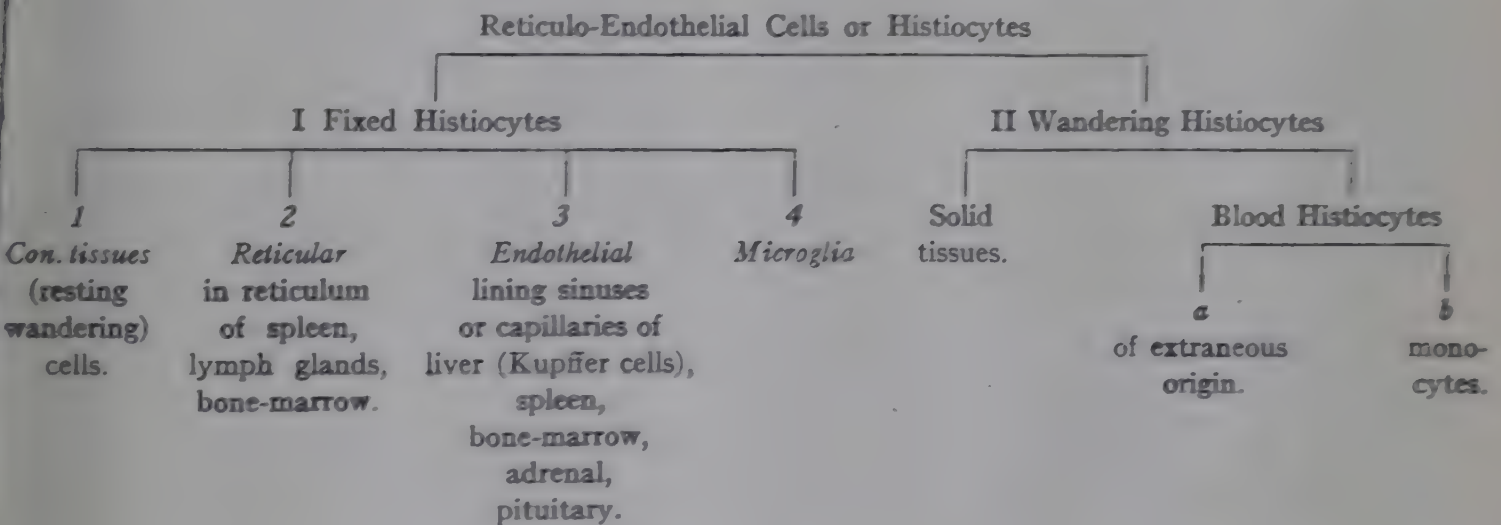

II. Wandering R.E. cells or free histiocytes

(1) **OF THE SOLID TISSUES.** From the foregoing it is seen that many of the fixed histiocytes may upon occasion become actively motile. Large cells of this type are found in the general connective tissues, in the peritoneum, in the splenic pulp and in the lymph glands, bone marrow, etc. (fig. 26). The wandering cells may on the other hand come to rest and become fixed for a long time. On account of the many different forms which these wandering macrophages may assume as a result of an inflammatory stimulus (p. 82) Maximow has named them *polyblasts*.

(2) **OF THE BLOOD.** (a) *Of extraneous origin.* Under certain circumstances as a result of some intense pathological stimulus (e.g., leukemia, bacterial endocarditis), the ordinary tissue macrophages already mentioned may be found in large numbers in the blood stream. They arise chiefly from the spleen and bone-marrow and swarm into the venous system, but rarely

like the fibroblast and has no characters in common with the so-called endothelial cells of the sinuses of the bone marrow, spleen, etc. These are called *littoral* (shore) *cells* by Maximow. They are relics of the primitive endothelium.

From the account of the histiocytes which has been given it is quite evident that phagocytosis is one of their chief functions. In this they constitute one of the most important and powerful means by which the defense of the body is sustained. Their action though similar to that of the neutrophilic leucocytes is less mobile and more localized in character. They, with the aid of the lymphocytes, contribute toward the repair process which follows the acute phase of a tissue injury. The various types are for the most part readily transformable, one into another, the different

reach the arterial side, for, on account of their huge size (30μ) they are strained out by the capillaries of the lung. Large numbers may be obtained from the right heart but few if any from the left.

(b) *Monocytes* (see p. 70). The origin of these normal elements of the blood has been the subject of considerable controversy. According to some, they arise solely from histiocytes, especially of the spleen and bone marrow, and are therefore classed with the reticulo-endothelial system. Lewis has shown that in hanging drop cultures macrophages may be transformed into monocytes, or vice versa. Maximow, on the contrary, believes that the monocytes arise from lymphocytes, stating that in certain situations, e.g., in the spleen, all transitional stages from lymphocyte to monocyte may be seen.

FUNCTIONS OF THE RETICULO-ENDOTHELIAL SYSTEM

The word "endothelial" is not quite appropriate. The cells lining the blood sinuses are not true endothelial cells. The ordinary endothelial cell of the blood vessels is a highly differentiated cell

forms which they assume being determined by local environmental conditions and the nature of the stimulus. Any of the stationary cells may change into wandering histiocytes (macrophages) or mobile cells may become fixed and either retain in the sessile state their special phagocytic properties or lose these entirely and become converted into the ordinary connective tissue elements—fibroblasts—or into epithelioid cells. The fibroblasts, however, never undergo the reverse change and assume ameboid characters; once formed they remain fixed. According to Maximow, lymphocytes may give rise to macrophages. The latter, however, never give rise to lymphocytes.

In chronic inflammation or in the repair stage of an acute process, the histiocytes play an important rôle. Some (the so-called *dust cells* of the lung) are responsible for the removal of foreign particles which have been carried into the pulmonary alveoli by the inspired air. The ability of the Kupffer cells to take up ingested thorium dioxide (thorotrast) which is opaque to the

X rays is made use of to delineate the liver in the living subject. The spleen, placenta, ureter and kidney pelvis, the vessels of the extremities or of the brain and the cerebral ventricles, can also be outlined radiographically by means of this agent. The administration of thorotrast is not, however, free from danger. It is radioactive, the alpha ray activity of 25 cc. of thorotrast being equivalent to that of 1 microgram of radium which is sufficient to produce pathological changes in susceptible persons. Thorium dioxide is eliminated from the body in insignificant amounts, almost all being permanently stored in the reticulo-endothelial cells of the bone marrow, spleen and lungs, as well as in the Kupfer cells, and even though no deleterious effects result from its radioactive properties it sets up a proliferation of connective tissue by acting as foreign material.

The epithelioid and giant cells of certain specific inflammatory processes, e.g., tubercle, which are derived from the histiocytes is but another instance of the latter's protean nature, and it is owing to these activities that the tissues are rendered so remarkably adaptable and plastic in their reactions to altered conditions. The omentum for example has long enjoyed a reputation as a protective structure, owing to its ability to form adhesions which serve to seal perforations of the gastro-intestinal tract or to isolate infected regions within the abdominal cavity. The omental tissue is particularly richly supplied with both stationary and wandering histiocytes. It contains also, even in health, immense numbers of lymphocytes, which, in part, are derived from division of their own kind locally, and, in part, have come from the blood stream. Normally the presence of these various cells in such numbers gives an appearance closely resembling a defense reaction—the "physiological inflammation" of Rossie. Histiocytes and lymphocytes are continually being cast in showers into the peritoneal cavity at all times but to a much greater extent in irritative conditions. Monocytes have been studied in transparent chambers inserted into the tissue of the rabbit's ear. They have been observed to leave the circulation and to become motile and phagocytic, and otherwise indistinguishable from tissue histiocytes.

The formation of bile pigment (p. 459) and the final destruction of the blood cells (p. 56) in the spleen are other well established functions of the histiocytes. The reticulo-endothelial system is also believed to be concerned with antibody formation.

In certain pathological conditions, the lipemia of diabetes, Gaucher's disease and Niemann-Pick's disease (p. 56) the reticulo-endothelial elements, especially of the spleen, are markedly increased in number and become loaded with lipid material.

THE BLOOD-FORMING ORGANS OF POST-NATAL LIFE

Red cells, granulocytes and possibly platelets are formed in the bone marrow, and lymphocytes

in the lymphoid tissue. The stroma or reticulum of these structures is the essential blood-forming tissue. The latter consists of (1) a fine net of cylindrical or ribbon-like fibers which can be stained by silver preparations and (2) large *reticular cells*—which are fused together by branching processes to form a loose network; the latter is intimately associated with the network of (1) which appear as reinforcing strands. The *reticular cell* (embryonic reticular cell, p. 7) is the nearest approach in the adult body to the primitive mesenchyme cell. The blood-forming capacity of the myeloid and lymphoid tissues depends upon the ability of these cells to become hemocytoblasts which in turn, according to the environment in which they are situated, are capable of developing into red cells, granulocytes, megakaryocytes on the one hand or lymphocytes on the other.

THE BONE MARROW

It is the red marrow situated in the ends of the shafts of the long bones such as the femur, humerus, and to a greater extent in the sternum, vertebral bodies and cranial diploë in which the blood forming functions are performed (fig. 1). The total volume of the red marrow of the body equals or exceeds that of the liver. It amounts to about 1400 cc. The shafts of the long bones are filled for the most part with yellow marrow, composed of connective tissue and fat; this is non-hemopoietic. In early childhood red marrow occupies the medullary cavity of the long bones and even in adult life the fatty marrow retains the essential reticular structure of hemopoietic tissue and so is capable of blossoming into red marrow under suitable stimulation. So, under certain conditions, for example in pernicious anemia, up to a much less extent during residence at high altitudes, the red marrow is increased in amount. It encroaches upon the medullary cavity of the shaft replacing to a greater or less degree the fatty tissue.¹ In aplastic anemia on the other hand the fatty marrow increases at the expense of the red marrow.

Drinker has shown that the circulation of the marrow is closed, i.e., the blood and the reticular tissue are separated by a complete membrane. This is contrary to the older view that the blood

¹ In some cases of rapidly developing anemia droplets may appear in the peripheral blood, and in some cases of hemorrhage the fatty acids of the blood increase. These facts suggest a dispersal of the medullary fat in order to make room for an extension of blood forming tissue—the red marrow.

into direct contact with the marrow cells through gaps in the capillary walls. The vascular bed of the marrow is a mesh-work of small blood spaces (sinusoids) lined by flat endothelial-like cells similar in character to those lining the sinuses of the spleen (p. 55). Not all the sinusoids, however, are open at one time. It has been estimated

Doan that the marrow contains a great many more of these vessels than could possibly be accommodated within the resistant bony encasement, where they all in the dilated state. Some of the sinusoids are completely collapsed and impervious to the blood. Others are dilated but, owing to

FIG. 27. Bone marrow from the upper epiphysis of femur of a child of six years; *a*, the fibrous network of the wall of a vessel from the surface and, *b*, in cross section; *c*, lining cells of the sinuses (littoral cells); *Emy*, eosinophil myelocyte; *Eos*, eosinophil leucocytes; *Erb*, erythroblast; *Erc*, erythrocytes; *Fc*, fat cells; *Meg*, mega karyocyte; *Nlk*, neutrophil leucocytes; *Nmy*, neutrophil myelocytes; *R*, reticular fibers (black with silver); *Sc*, nuclei of the primitive reticular cells; *V*, venous sinusoids (after Maximow and Bloom).

the vessels which lead to and from them being constricted, they are isolated from the general circulation. Regions of low oxygen tension are in this way provided. It has already been pointed out (p. 9) that a low oxygen tension serves as a stimulus to red cell formation.

The blood cells, if the observations of Maximow be accepted, are formed extravascularly and subsequently enter the blood stream.² Their pressure upon the endothelial wall causes its erosion or rupture and the cells invade en masse the lumen of the sinusoid where further growth and maturation of the cells follows. Finally through the

² Sabin, Doan and others contend that only the granulocytes have an extravascular origin, the erythrocytes being derived, not from reticular cells but from the endothelial elements (littoral cells of Maximow) of the marrow capillaries.

opening up at certain periods of the vessels leading from the hemopoietic region, the mature cells escape into the general circulation. The sudden showers of young cells that occur in pernicious anemia (blood crises) may be explained by a process of this nature. That the delivery of red cells into the circulation is normally intermittent is also suggested by the fact that the red cell count is not constant but shows a diurnal rhythm the highest counts occurring in the morning hours. There may be a difference of 300,000 cells or so between the maximal and minimal daily levels of the red cell count. Normally no cells enter the general blood stream until maturation is practically complete. Drinker for instance was unable to cause the passage of immature forms into the blood by prolonged perfusion of the marrow or by muscular exercise. The perfusion fluid evidently was unable to open a way into these isolated pools and wash out the immature forms. From the work of Krogh and of Lewis on the capillary circulation in other situations this result is not unexpected (p. 264).

THE MATURATION OF THE BLOOD CELLS

(a) Erythrocytes—Erythropoiesis

The red cells pass through several stages before they attain full maturity. In the examination of a simplified (hypoplastic) marrow, such as may be induced in the pigeon by underfeeding or in mammals after poisoning with benzol, most of the stages can be followed (cf. fig. 28 and frontispiece). The reticular cell, as we have seen, gives rise to the *hemocytoblast*. The latter divides into two daughter cells which stain deeply with basic dyes. These are called *basophilic erythroblasts* by Maximow; they contain no hemoglobin. The next stage which may be distinguished is, following Maximow's terminology, the *polychromatophil erythroblast*. The earliest cells of this stage are large, with a large, round and often vesicular nucleus; their cytoplasm is rich in basophilic material but also contains traces of hemoglobin. The hemoglobin concentration increases in amount as development advances, the more mature cells being well supplied with pigment. Hemoglobin is acidophilic, so the cells of the erythroblast stage, since they have retained a relatively large amount of basophilic substance, stain with both acid and basic dyes. This property of dual staining, known as *polychromasia*, diminishes again as the cells mature beyond the erythroblastic stage and gradually lose their basophilic material.

Several authors (Sabin, Dean and associates) distinguish three types of cells during this stage of development—the *megaloblast* and the *early* and *late erythroblasts*. The megaloblast of these authors corresponds to the youngest of the polychromatophil erythroblasts mentioned above, i.e., a large nucleated cell which, owing to its relatively large proportion of basophilic material, shows only a very slight tendency to polychromasia. Maximow avoids the term megaloblast, advising that it be reserved for the large cell of pernicious anemia to which it was originally applied. He claims that the latter cell, though resembling the primitive

in the marrow that they become discharged in the general blood stream.

In healthy marrow the multiplication of red cells which occurs to replace those lost from circulation through wear and tear is effected almost entirely by the division and redivision of late forms, i.e., of normoblasts and older erythroblasts (homoplastic development) and to a negligible extent through the multiplication and subsequent maturation of the more primitive forms. The youngest erythroblasts (megaloblasts), for example, in normal marrow are absent or amount no more than 0.01 to 0.04 per cent of the total nucleated red cell elements, according to Sabin; the older erythroblasts make up about 30 per cent and the normoblasts 70 per cent or so. In pernicious anemia, on the other hand, large numbers of megaloblasts are present. In this disease erythropoiesis appears to have reverted to a more primitive type—or, as it is expressed, “shifted to the left” (heteroplastic development). The benefits of liver therapy apparently depend upon the power of the hepatic principle to restore the normal mode of red cell development.

(b) Granulocytes—granulopoiesis

The earliest stage in the differentiation of the granulocytes from the primitive reticular cell in the marrow is that of the so-called *myeloblast*. It is generally agreed that the origin of the granulocytes is extravascular and that they pass into the marrow vessels only after they acquire motility. Maximow considers the myeloblast to be nothing more or less than the polyvalent hemocytoblast or stem cell, identical with the large lymphocyte, the minute differences in structure between it and the latter being due it is thought to the environment in which it is placed, i.e., the bone marrow. Here it gives rise to the three types of granulocytes. The myeloblast is given special interest since it is the predominant cell in the blood and marrow in certain forms of *leukemia* (p. 86) when it may constitute 90 per cent of the white cells. It constitutes only a very small percentage of the cells in normal marrow.

After the stage of the myeloblast a few specific granules begin to appear in the cytoplasm which at the same time becomes less basophilic in character. Also present are a few anisotropic granules. In the subsequent history of the cell up to its discharge into the circulation four stages, based upon the development of specific granulation and the reduction in basophilic material, are recognized. The cells of the first three of these stages

FIG. 28. Diagram showing maturation of the red cells. The view of Sabin, Dean and associates is indicated by the bracketed terms (see footnote, p. 85). As mentioned in the text the early and late erythroblasts of these observers are termed polychromatophil erythroblasts by Maximow. This term has been omitted from the diagram for the sake of simplicity provided from Sabin.

cell of normal marrow is probably not identical with it.

The older erythroblasts give rise to normoblasts. The normoblast, as the name itself implies, resembles the mature erythrocyte in size and hemoglobin content but still retains its nucleus which, however, shows condensation of its chromatin material (pyknosis) and stains more deeply. In the final stage of the maturation process, the nucleus is extruded from the cell and the now practically mature erythrocyte is discharged from the marrow into the general circulation. It betrays its youth only by a fine basophilic reticulation of its cytoplasm and is therefore called the *reticulocyte* (p. 12). It is probably not until the reticulocytes have reached a certain concentration

termed *myelocytes A, B and C*, respectively. Cells of the fourth stage are called *metamyelocytes* (fig. 29). In the youngest stage the granules, mentioned above, are very few³ and are in lesser numbers in myelocyte B and in maximum quantity in myelocyte C. The nucleus in these is oval or spherical and shows no attempt of lobulation. The metamyelocyte is characterized by slight indentation of the nucleus and the evidence of typical ameboid movement. Finally the nucleus becomes deeply indented or constricted at one or more points and is discharged into the circulation as a young leucocyte (neutrophil, eosinophil or basophil). This is the first stage of Arneith mentioned on page 71. It is also referred to by Schilling as the older metamyelocyte or the band cell. As shown in figure 29 three levels of development are distinguished. Level I extends from the reticular cell to, and includes, the myeloblast. Level II embraces the myelocyte and the metamyelocyte; cells at this level multiply actively and have the power of growth. Level III includes those forms present in normal blood (Arneith stages); the cells have lost the power to divide and grow.

The oxidase reaction (p. 73) depends upon the presence of specific granules. The myeloblast therefore does not give this reaction and the youngest myelocyte (A) responds in proportion to the number of granules which it contains; these may be very few and difficult of detection. The later myelocytes of course give a positive reaction. As in the case of erythropoiesis the earliest stages of white cell development—myeloblastic and early myelocytic—are little in evidence in normal myeloid tissue. The leucocytes are supplied to the blood through the division and redivision of the later forms of white cell elements—i.e., the myelocytes. A census taken of the colorless elements of the marrow in normal rabbits gives an average of about 1 per cent myeloblasts, 90 per cent myelocytes C and metamyelocytes, of which the great majority were neutrophilic, and about 10 per cent young leucocytes. Younger myelocytes make up the balance. The number of leucocytic elements is three times greater than the number of red cell elements—erythroblasts and normoblasts. The ratio of granulocytes to red cells in blood on the other hand, is 1 to 600. The differ-

This cell, myelocyte A, resembles so closely its progenitor the myeloblast and represents a transition stage between the latter cell and the older myelocyte that it is often referred to as the promyelocyte. Some use this latter term to include also myelocyte B.

ence in the cell ratios in marrow and in blood is ascribed to the greater mortality of the leucocytes and the consequent necessity for a greater hemopoietic activity in order to replace them.

In myeloid leukemia the process of granulopoiesis, is pushed back to a more embryonic type and immature forms appear in the blood. The marrow picture indicates a great activity of the early myelocytic and myeloblastic stages. The marrow of the fetus and to a less degree that of the new-born show also a relatively large proportion of immature cells.

(c) The platelets

These are generally stated to arise from giant cells of the marrow (40μ or more in diameter) known as megakaryocytes. The latter have an

FIG. 29. Diagram showing maturation of the granulocytes. Bracketed terms are those of Sabin, Doan and associates (modified from Sabin).

irregular, ring-shaped nucleus, and are capable of ameboid movements. It was first suggested by Wright that fragments of their protoplasm became detached to form the blood platelets. Normally, the marrow contains only a few of these cells, but it has been stated that an increase or decrease in their number is followed by corresponding changes in the number of circulating platelets.⁴ Howell

⁴Wright's view of the origin of the platelets from megakaryocytes is not, however, universally accepted. Various views are held with regard to the genesis of the platelets, some believing them to be formed from the cytoplasm of leucocytes, and others that they are simply precipitates from the plasma. Several observers have expressed the belief that they are fragments of degenerated red cells. In support of this view Watson reports the observation that phenylhydrazine which damages the erythrocytes causes a sharp rise in the platelet count and a reduction in the number of red cells. This observer also found that, when erythro-

and Donahue have concluded from their experiments that the platelets are derived from megakaryocytes in the lungs. They base their view on the finding that both in cats and in man the platelet count is somewhat higher in arterial than in venous blood. The ratio of platelets to erythrocytes in arterial blood is 1:21.4, as compared with 1:25.8 in the blood of the corresponding vein, which implies that platelets are destroyed or removed from circulation in the capillaries and replenished in the lungs. Further evidence was derived from the observation that a smear of lung tissue shows large numbers of giant cells, whereas only a few are found in a similar specimen of bone marrow. It is probable, however, that the lung megakaryocytes do not originate in the lungs but have their source in the bone marrow and, owing to their large size, are merely trapped in the pulmonary capillaries.

(d) *Lymphoid tissue and the formation of lymphocytes*

The central areas of the follicles in lymphoid tissue (lymph glands, spleen, etc.) stain more lightly with the ordinary stains than the peripheral zones. These lighter areas, about 1 mm. in diameter and pierced near the center by a small arteriole, are generally known as the "germ centers." In the embryo and in new-born animals the earliest stage in the development of the lymphocytes is represented in lymphoid tissue as in the bone marrow by a large lymphocyte or hemocytoblast. It is analogous and practically identical in structure with the myeloblast. By some it is called the *lymphoblast*. It arises from the undifferentiated primitive reticular cell of the lymphoid stroma similar to that in the marrow from which the myeloblast and, according to Maximow, the erythroblast arise but as in the case of the myeloid cells the lymphocytes normally arise from the division of cells of later stages.

An interesting experiment of Maximow's supports the view that the large lymphocyte is the common precursor of the granulocyte and lymphocyte and that the course of development which

the stem cell shall follow is determined by its immediate environment. Lymphoid tissue was cultured in an environment prepared to simulate that of the bone marrow by the use of a preparation of blood plasma and marrow extract. Proliferation of the large lymphocytes and their differentiation into myelocytes were clearly observed.

(e) *The origin of monocytes (see p. 81)*

THE LEUKEMIAS

In these conditions the number of white cells usually enormously increased and may reach a count of 1,000,000 per cubic millimeter. The red cells are reduced.

On the basis of the type of white cell predominance in the blood two main forms of the disease are recognized—the *myeloid or myelogenous* and the *lymphatic*. Either of these may be chronic or acute.

MYELOID LEUKEMIA (SYNONYMS; MYELOGENOUS SPLENO-MEDULLARY, MYELOCYTIC LEUKEMIA)

In the *chronic form* the white cell count is very high, frequently running into the hundreds of thousands per cubic millimeter. The predominant cell is the neutrophilic myelocyte though eosinophilic and basophilic myelocytes and myeloblasts (2 to 3 per cent) are also present in smaller numbers. The spleen is enlarged, often greatly, and the yellow bone marrow is replaced by a grayish pink richly cellular tissue.

In the *acute form* of the disease the myeloblasts, or rather myelocytes A (promyelocytes) dominate the blood picture. The condition is usually referred to as *acute myeloblastic leukemia*. There is pronounced anemia and immature red cells appear in the blood.

LYMPHATIC LEUKEMIA

In the *chronic form* the predominant cell is the small lymphocyte. These average around 100,000 per cubic millimeter. Enlargement of the lymph glands and general hyperplasia of lymphoid tissue occur. The spleen is increased moderately in bulk.

In the *acute form* of lymphatic leukemia the blood contains large numbers of both small and large lymphocytes. These latter, according to Maximow's view, may be regarded as hemocytoblasts and so the forerunners of small lymphocytes just as the myelocytes found in myeloid leukemia is an immature granulocyte. Since the large lymphocyte and the myeloblast are identical, i.e., they are both hemocytoblasts exposed to different environmental conditions, it is very difficult to distinguish the so-called myeloblast (myelocyte A) in myeloblastic leukemia and the large lymphocytes in acute lymphatic leukemia. The oxidase reaction is sometimes employed in an effort to make the distinction but as a rule is unsuccessful since the youngest myelocytes also frequently fail to give a definitely positive response.

cytes were suspended in a counting chamber, degeneration of the red cells occurred while bodies indistinguishable from platelets appeared. Furthermore, the platelet count, as shown by Bodson, is increased by splenectomy, or by "blackening" the reticulo-endothelial macrophages (which, as we have seen, engulf red cell fragments) by injections of India ink. The term "blackening" refers to the overloading of the reticulo-endothelial cells with the ink particles and the consequent suppression of their phagocytic properties.

In some instances of leukemia the total white cell count is not increased (it may be diminished) but the proportion of lymphocytes or granulocytes, respectively, raised and immature forms appear. This variety of disease is spoken of as *a-leukemic leukemia*.

Monocytic leukemia is a third and unusual type of disease in which the blood picture is dominated by monocytes. These are recognized by supravital staining (p. 80) with neutral red—when a rosette-like arrangement of the dye particles appears in the cytoplasm. The oxidase reaction is of course negative.

PATHOGENESIS

The cause of leukemia is unknown. In the two common types of the disease—myeloid and lymphatic—

the formation of the immature cells in the majority of instances is concentrated respectively in bone marrow and lymphoid tissue. In the chronic myeloid form myelocytes are formed in the spleen as well. The great enlargement of the spleen in this form is due partly to the phagocytic activity of this organ which is called upon to remove a much greater number of degenerated leucocytes than usual and partly to the manufacture of immature cells. From what has been said in previous pages of the varied potentialities of the stem cell it is evident that either type of cell may also arise from any situation in the body in which reticular cells exist. Thus lymphocytes may arise in the lymphoid tissue of the spleen, or lymph nodes, or either type of cell may arise in the general connective tissues.

CHAPTER XII

THE COAGULATION (CLOTTING) OF BLOOD

GENERAL DESCRIPTION OF THE CLOTTING PROCESS

If blood be collected into a test tube it will be found at the end of 5 or 6 minutes that it has lost its fluidity and has set into a jelly. The tube may be inverted, but the blood, which is now said to have *clotted* or *coagulated*, does not escape. If it were possible to magnify this clot many times and to look within it, one would see a mesh of very delicate fibrils, among which were entangled, as in a net, the red and white cells and many fragmented platelets. The fibrils can be readily revealed if a thin section of the clot be examined under the high power of the microscope. They are composed of *fibrin* formed by the conversion of the fibrinogen from a soluble (hydrosol) into an insoluble form (hydrogel). The fibrin as it forms is deposited as very fine needle-shaped crystals. If the clot is permitted to stand for an hour or so, it will be found to have shrunk, and in shrinking to have expressed from its interstices a clear, faintly straw-colored fluid. This is the *serum*. The latter remains perfectly fluid and is totally incapable of clotting. The shrinking and condensation of the clot is due to the gradual shortening of the fibrin threads which enmesh the corpuscles. In this retraction of the clot or *syneresis*, as it is termed, the platelets play an essential rôle. Though numbers of platelets undergo disintegration when the blood is shed (see below), others become attached here and there in groups or knot-like clumps to the fibrin threads, and in some unexplained way cause bending and shortening of the latter. Clots formed in blood deficient in platelets are soft and friable, and do not contract in the normal way. It used to be thought that the intact platelets which were seen in sections of blood clots served as nuclei from which the fibrinogen to fibrin conversion started, but it has been demonstrated by Tocantins that the platelets take up their positions *after* the fibrin has formed. The full retraction of the clot and the separation of the serum ordinarily takes a considerable time, but separation can be brought about within a few minutes by rapid centrifuging.

If the blood be centrifuged as soon as it is shed and the cells in this way separated from the plasma, a clot forms in the latter, due as before to the formation of fibrin threads. After a time the

colorless clot shrinks and, as in the case of whole blood, expresses the transparent serum. The clotting process is therefore essentially a phenomenon of the plasma. The so-called "buffy coat" which forms in the upper layers of blood when it clots slowly, and so allows a certain degree of sedimentation of the cellular elements to occur, is the clotted plasma.

THE CLOTTING MECHANISM

In the very intricate mechanism underlying the coagulation of blood the following substances take part. (1) *Prothrombin*, (2) *thrombin*, (3) *thromboplastin* (or *thrombokinase*), (4) *ionic calcium* and (5) *fibrinogen*. By the action of thromboplastin, prothrombin, which is inactive, is converted in the presence of calcium ions into the active thrombin. Thrombin, an enzyme, then acts upon the soluble fibrinogen of the plasma to convert it into the insoluble fibrin spoken of above, forming threads in which the solid elements of the blood are enmeshed. Thus the clot is formed.

Under normal circumstances the blood remains fluid in the vessels not, as was thought at one time, because it is in motion, but most probably because thromboplastin is present in circulating blood in only very small amounts and, as a consequence, the active enzyme thrombin is not produced and fibrin is not formed. Any small amount of thrombin which might arise in the blood is neutralized by an antithrombin. This latter material, the so-called *normal antithrombin* of the plasma, is present in low concentration in mammalian blood but in much larger quantities in the blood of birds. According to Quick, it is closely associated with the albumin fraction of the plasma.

When blood is shed, thromboplastin is liberated from the injured tissues or from the fragmentation of platelets, thus the clotting mechanism is initiated.

The modern conception of the clotting process is outlined in its simplest possible terms in the following scheme.

s, only four *primary factors*, prothrombin, thromboplastin, ionized calcium and fibrinogen are required for the coagulation of blood.)

Ferguson found that during the process of activation of prothrombin by calcium and thromboplastin, there is a stage lasting for a few minutes in which the removal of calcium (by the addition of oxalate) causes inactivation of the newly formed product ("fresh" thrombin). After the thrombin is fully elaborated ("ripe" thrombin), except for a slight delay just mentioned, the removal of calcium ions does not affect the coagulant action. He believes that this difference in the effect of calcium lack upon "fresh" and "ripe" thrombin indicates the formation of an intermediate complex in the production of thrombin from prothrombin. Ferguson concludes that thrombin is a calcium-thromboplastin-prothrombin complex or compound.

Heparin. (The action of certain impure extracts of liver in inhibiting the coagulation of blood was discovered by McLean, a pupil of Howell, in 1916. Later, a series of studies was carried out by Howell and Holt upon extracts of liver from which they obtained a powerful anticoagulant. They gave it the appropriate name of *heparin*. Howell and Holt obtained their material from dog's liver, but it has since been prepared in larger quantities by Charles and Scott from beef liver. Lung, muscle and intestinal wall also contain it in relatively large amounts. Smaller quantities are contained in spleen, heart and thymus. It is present in negligible quantities in serum. When heparin is injected into the living animal the blood remains incoagulable for many hours. A unit of heparin is defined as the quantity of material which will prevent for 4 hours the clotting of 1 cc. of cats' blood when kept in the cold. A very potent crystalline preparation has been obtained from beef liver by Scott and Charles. This contains nearly 100 units per milligram.)

Jorpes found that like certain other anticoagulants, such as azo dyes and germanin, the heparin molecule contains sulphuric acid groups, in virtue of which it acts as a relatively strong acid. It belongs to the same chemical group as that to which mucic acid and chondroitin sulphuric acids belong. Anticoagulants have been prepared by Chargaff and his associates by the introduction of sulphuric acid groups into such polysaccharides as cellulose, glycogen and starch and into the cerebrosides, cerebrin and kersin.

The anticoagulant action of heparin is due mainly to its being a powerful *antithrombin*, i.e., its property of inactivating thrombin. Its

antiprotrombin action, i.e., its ability to prevent or inhibit the conversion of prothrombin to thrombin has been doubted, but the experiments of Ferguson provide evidence for such an action which is due apparently to its neutralization of the action of thromboplastin—an essential factor in the initial phase of the clotting process. Thromboplastin also neutralizes the antithrombin action of heparin. Therefore, when thrombin and heparin are present in suitable proportions to maintain the fluidity of a sample of blood, the addition of thromboplastin causes coagulation. The result is not influenced by the presence of calcium salts.

Heparin is present only in minute amounts in the circulation, and at any rate is not responsible for the maintenance of the fluidity of the blood in the living body. The most probable reasons that the blood does not clot intravascularly is, as already mentioned, because thromboplastic material is not available in sufficient amounts to convert the prothrombin to thrombin and because an antithrombin other than heparin exists in the circulating blood.¹

From the evidence procured by Wilander, heparin appears to be a product of the mast cells (mobile basophil cells of the tissues) which may be seen in clusters around the minute vessels of those tissues which give a high yield of heparin. Mellanby suggests that the significance of heparin in tissues is that it serves as a *local* anticoagulant, preventing the clotting of blood in the small vessels.

Chargaff and Olson found that protamine (salmine) annuls the action of heparin both *in vitro* and *in vivo*. Protamine, a simple protein with basic properties (see also p. 539 and p. 580) combines with heparin, the resulting compound being free from anticoagulant action. Thus it is possible to determine the quantity of heparin in a sample of blood by ascertaining the quantity of protamine required to give the shortest coagulation time. By this means the great lengthening of the coagulation time in anaphylaxis (up to 2 days or more) and peptone shock has been shown by Waters, Markowitz and Jaques to be due to the high concentration of heparin in the circulation (p. 92). Heparin is most effective when admin-

¹ According to Quick, heparin does not in itself act as an antithrombin but merely intensifies the action of the normal antithrombin of blood (namely, serum albumin) to produce a powerful anticoagulant. Quick also claims that heparin is not neutralized directly by thromboplastin but that the apparent neutralization is due to the acceleration by thromboplastin of the production of thrombin from prothrombin.

istered intravenously, much larger doses being required when it is given by subcutaneous injections. Besides its action in prolonging the coagulation time, heparin, as shown by Murray, Jaques, Perrett and Best, hinders the agglutination and deposition of platelets and thus discourages thrombus formation. Heparin has been recognized for a number of years as a valuable anticoagulant for use in physiological experiments but it is only comparatively recently that purified preparations suitable for clinical use have become available. Its most important field of usefulness is in blood transfusions, in operations upon the blood vessels and to check the extension of certain types of thrombosis. Its employment as a preventive against postoperative and other thrombotic conditions which carry the threat of fatal pulmonary embolism (p. 96) has been advocated by several investigators (Howell, Mason, Hedenius, and Murray and associates). Widstrom and Wilander have suggested its use to prevent the formation of fibrinous adhesions in pleurisy; in heparinized rabbits the inflammatory exudate caused by the injection of iodine into the pleural cavity is incoagulable.)

THE PROPERTIES OF PROTHROMBIN AND THROMBIN AND OF THROMBOPLASTIN

Prothrombin and thrombin, according to Seegers, are carbohydrate-containing proteins. This investigator has prepared from beef plasma highly potent preparations of these agents which contain, respectively, 300 units of prothrombin activity and 600 units of thrombin activity per milligram. At a pH of 7.0 prothrombin and thrombin are highly soluble in water or physiological saline, it being possible to prepare a 60 per cent solution of either material. Prothrombin is insoluble at a pH of 4.9 and thrombin at about 4.3. Both substances are completely and permanently inactivated by acid (pH 3.5) and by alkali (pH 11.0). They are destroyed by heating to 60°C. for 30 minutes.

Quick has secured evidence that prothrombin is a complex, consisting of two components (A and B) combined through calcium. Component A is reduced, presumably through oxidation, by oxalate. Component B is destroyed by dicumarol, and possibly also as a result of a deficiency of vitamin K. Component A disappears from stored plasma. In hypoprothrombinemia it is usually only component B which is reduced.

The origin of prothrombin. The liver is probably the chief source of prothrombin, though the experi-

ments of Drinker point to its being produced to some extent as well by the bone marrow. This observer obtained a fluid rich in prothrombin by perfusion of the bone marrow. The production of prothrombin is governed by vitamin K (p. 660).

Thromboplastin is present in all tissues, lung and brain being especially rich sources. It is soluble in fat solvents and, according to Howell, is identical with or closely allied to the phospholipid, *cephalin*.

HEMORRHAGIC TENDENCIES DUE TO HYPOPROTHROMBINEMIA

Depression of the prothrombin level in the blood—*hypoprothrombinemia*—occurs under several conditions, such as vitamin K deficiency and severe liver damage. A bleeding tendency is not shown, however, according to Quick, until the prothrombin concentration falls to about 20 per cent of the normal. Other observers, however, place the critical level somewhat higher.

Hemorrhagic disease of the newborn has been shown quite definitely to be the result of a low prothrombin concentration. At birth and up to 6 hours thereafter, the prothrombin level is not far below normal, but apparently the baby comes into the world with a small reserve. This tends to become quickly exhausted, so that the prothrombin concentration may reach a dangerously low level at the end of 24 hours. This physiological hypoprothrombinemia is due to lack of vitamin K. When the infant commences to take food, bacteria are introduced into the intestinal tract which, acting upon the contents of the intestine, synthesize the anti-hemorrhagic vitamin (p. 660) and the hypoprothrombinemia is corrected automatically. Should the hemorrhagic state develop it is quickly arrested by the administration of vitamin K. Large doses may be given to the mother in the later months of pregnancy as a preventive. Hypoprothrombinemia and a hemorrhagic tendency also occur in diseases, e.g., acute yellow atrophy, associated with severe liver damage, in certain intestinal diseases, e.g., sprue and ulcerative colitis, and in the hemorrhagic disease of farm animals caused by eating spoiled sweet clover. In the animal disease the low prothrombin level is due to a toxic substance (*dicumarol*). The mode of action of this agent is not altogether clear. In therapeutic doses it does not damage the liver, though in large doses it may, and its anticoagulant action is then enhanced as a result of the depression of prothrombin production. Quick states that it reduces the B component of prothrombin.

The bleeding tendency which for years has been recognized to be a feature of obstructive jaundice or when bile is lost to the exterior through a biliary fistula has been shown to be the result of vitamin K lack. The deficiency is not due, however, to any dearth of the vitamin in the intestinal tract, but simply to the absence of bile salts without which the vitamin cannot be absorbed into the blood stream (p. 660). The prothrombin disappears from blood stored for transfusion purposes but it is questionable whether the fact is of much practical importance, provided that the production of this factor by the liver is not depressed.

Determination of the shortened coagulation time as an index of the prothrombin concentration. Prothrombin time. Quick's method is as follows. Nine volumes (about 5 cc.) of blood obtained from a vein is decalcified (p. 000) by the addition of one volume of a 0.1 mol solution of sodium oxalate. In a small test tube 0.1 cc. of the oxalated plasma is mixed with 0.1 cc. of thromboplastic material (prepared from fresh rabbit's brain or viper venom) and recalcified with 0.1 cc. of 0.025 mol solution of calcium chloride. The time from the addition of the calcium to when the clot forms is recorded by a stop watch. The test is carried out in a water bath at 37.5°C. The prothrombin concentration in per cent of the normal is calculated as follows:

$$\text{Prothrombin concentration} = \frac{K}{\text{c.t.} - a}$$

c.t. = clotting time; K, a constant = 302; a, a second constant = 8.7. Thus if the clotting time is 21 seconds the prothrombin concentration is $\frac{302}{21 - 8.7} = 25$ per cent of normal (approx.).

The prothrombin time is now utilized as a test for liver function.

The means used to prevent or retard coagulation—anticoagulants

(1) COLD. Since blood clotting involves the action of enzymes it is to be expected that coagulation will be retarded by lowering the temperature. Keeping blood at a temperature of from 5° to 10°C. postpones coagulation but does not absolutely prevent its occurrence. Cold, e.g., ice, etc., applied to the surface of the body as a measure for the arrest of hemorrhage has however little if any influence in retarding the coagulation process. As a matter of fact a hemostatic effect is brought about in such instances as a result of the vasoconstriction reflexly induced.

(2) AVOIDANCE OF CONTACT BETWEEN THE BLOOD AND FOREIGN MATERIALS OR INJURED TISSUES. Since thromboplastin is essential for blood coagulation any measure that will prevent injury to the platelets or that will prevent the blood from coming into contact

with the tissues will retard the clotting process. Receiving the blood directly from an artery or vein into a glass vessel free from dust or foreign material of any sort, especially if the inner surface be made smooth by a coating of paraffin, will slow the coagulation process. By this means the disintegration of the blood platelets is reduced to a minimum and contact with the tissue cells is avoided. The blood of birds collected in this way remains fluid indefinitely. That the necessary thromboplastin is present in the blood, but that some special means are required for its liberation, is shown by the fact that upon the addition of a small quantity of distilled water or of foreign particles to the drawn blood clotting at once ensues.

On the other hand, if the blood flows over a rough surface it causes greater fragmentation of the platelets and so hastens coagulation. The blood coming from a ragged wound which involves a greater destruction of tissue, is also likely to clot more quickly than if it issues from a blood vessel that has been cleanly incised, as by a scalpel or a razor. The contact of a sponge or a powdered substance to the wound by increasing the extent of surface exposed also hastens the formation of the clot.

(3) DE-CALCIFICATION OF THE CLOTTING MECHANISM. The addition of oxalate (sodium, potassium or ammonium) or of a fluoride to blood to the extent of 0.1 per cent or more completely destroys its power to clot spontaneously. In the former instance the calcium is precipitated as calcium oxalate. Oxalated blood recovers its ability to clot if shaken with chloroform, but the fibrin which forms redissolves after the blood has stood for a time. Fluoride does not precipitate the calcium but forms a weakly dissociated calcium compound. Sodium citrate also prevents coagulation. In this instance a double salt—calcium sodium citrate—is formed which again is only slightly dissociated. If calcium in the ionic form, e.g., the chloride, be added to the oxalated, fluoride or citrated plasma (recalcification), the power of the blood to clot is regained. Also the addition of thrombin or of thromboplastin to the decalcified blood causes it to clot. The restraining effect of citrates upon the clotting process was made use of during the last war for transfusion purposes. The donor's blood was received into a special transfusion bottle containing isotonic sodium citrate solution. Oxalates and fluorides on account of their intensely poisonous properties cannot of course be used in transfusion.)

(4) NEUTRAL SALTS. Magnesium sulphate solution in a strength of 27 per cent mixed in the proportion of 1 to 4 of blood postpones coagulation for some time, but does not prevent it indefinitely. Sodium sulphate in half saturated solution added to an equal quantity of blood has a similar effect, as has also a 10 per cent solution of sodium chloride in the same proportion. The manner in which these substances act is not clear. They do not decalcify the blood. That the activity of some or other elements necessary for the clotting

process is merely suspended and that none are destroyed, is shown by the fact that mere dilution of the "salted" blood is followed by clotting. Some think that these substances may act by preserving the platelets and corpuscles from disintegration and so hindering the liberation of thromboplastin. Zinc sulphate in 0.5 per cent solution prevents coagulation by precipitation of the fibrinogen. Sodium thiosulphate and germanin are anticoagulant, this action depending apparently upon their sulphur content.

(5) AZO-DYES, such as Chicago blue 6 B, Trypan red, Trypan blue, Chlorazol fast pink B.K.S. etc., are powerfully anticoagulant. Chicago blue, the anticoagulant property of which was discovered by Rous and his associates in 1930, is more potent either *in vivo* or *in vitro* than the earlier preparations of heparin. One milligram of purified Chicago blue will prevent for 60 hours the coagulation of 1 cc. of rabbit's blood kept on ice.

(6) CERTAIN SUBSTANCES OF A BIOLOGICAL NATURE.

(a) *Hirudin*, a substance secreted by the buccal glands of the leech and extracted commercially has a very powerful anticoagulant effect. It is a typical anti-thrombin, i.e., like heparin, it inactivates thrombin. *Hirudin* has been used extensively in the past to prevent coagulation during physiological experiments. (b) *Snake venoms*. The poisons of some snakes, particularly of the cobra, are powerfully anticoagulant. One hundredth part of a milligram per kilo of body weight will, according to Howell, entirely prevent coagulation. Its anticoagulant effect is thought to be due to some chemical change which is produced in the thromboplastin. The anticoagulant effect of cobra venom is probably intimately associated with its hemolytic action (p. 50). Some other snake venoms, however, have just the reverse effect and cause intravascular clotting. (c) *Heparin* (see p. 89). It is the most powerful of all anticoagulants of animal origin, being several times more effective than *hirudin*. (d) *Peptone solution* when injected prevents coagulation. According to Howell it acts by stimulating the liberation of heparin from the liver. Confirmatory evidence for this explanation has been furnished by others (Quick, and Waters and associates). Peptones also have an anticoagulant action when added to shed blood. The anticoagulant effect under these circumstances is ascribed by Mills and by Pickering to the increased resistance of the platelets to disintegration induced by the peptone solution. (e) In *anaphylactic shock* the blood remains incoagulable indefinitely (up to 2 days at least). Waters, Markowitz and Jaques have shown that this is due to the liberation of heparin from the liver. Anaphylaxis produced in hepatectomized dogs is not accompanied by a prolonged coagulation time. (f) *Cysteine* (see p. 466). (g) *Dicumarol*, an anticoagulant found in spoiled sweet clover. This material exerts its action by depressing the prothrombin concentration (p. 90).

Defibrinated blood

If blood be kept constantly stirred or be whipped by means of a faggot of fine twigs or wires, the fibrin gradually collects upon their surfaces. In this way all the fibrinogen in a short time becomes converted into fibrin which is removed as it is formed. The fluid which remains is composed of serum together with the red and white cells and resembles blood in appearance and consistency, but of course is totally incapable of clotting. Defibrinated blood is frequently used in physiological experiments instead of employing an anticoagulant. Though defibrinated blood closely resembles ordinary blood it frequently contains toxic substances developed during the clotting process and is, therefore, unsuitable for transfusion into man. The formation of fibrin is actually hastened by the whipping action, since the greater surface to which the blood is exposed and the violent agitation to which the cellular elements are subjected cause a more rapid abundant liberation of thromboplastin. Blood which has been extravasated into the pleural, peritoneal or other body cavity is usually found to be fluid, if any considerable time has elapsed since the hemorrhage occurred. Such blood is found to be incoagulable, for it has already clotted and then undergone a natural process of defibrination, the clots having been dissolved as a result of the digestion of the fibrin (fibrinolysis) by proteolytic enzymes. The fluidity of menstrual blood is caused in the same way. A fibrinolysin, although not present in normal blood under ordinary circumstances, appears in plasma after shaking with chloroform.

Substances which hasten the clotting process

(Adrenaline when injected hastens the clotting process. Emotional excitement, muscular exercise and hemorrhage act similarly probably through the liberation of the hormone from the adrenal medulla. Adrenaline has no effect upon the coagulation of blood after it has been shed.

The effects of thrombin and thromboplastin have been discussed. Tissue extracts especially those of lung and thymus which are rich in thromboplastin are powerfully coagulant, as are also the venoms of some species of snakes. The coagulant property of such venoms depends upon their containing a proteolytic enzyme which converts prothrombin to thrombin; the conversion occurs in the absence of ionized calcium.

Repeated injections of sodium citrate are also said to increase blood coagulability through the compensatory production, it is supposed, of a coagulant material within the body. Repeated injections of oxalates have a similar action.

COAGULATION TIME

(The coagulation time is the time which the blood takes to clot after it has been shed. Obviously, any condition which decreases the coagulability

the blood lengthens the coagulation time and vice versa.

A number of methods have been devised to determine the precise moment when clotting occurs. The clotting time as determined by different methods varies considerably since the index or criterion of coagulation is not the same in all, and the conditions to which the blood is subjected are also different. On this account the values are not absolute and the results obtained by different methods cannot be compared strictly with one another.

A simple but rough method when a considerable quantity of blood is available is to collect the blood into a small test tube and take as the coagulation time, the period elapsing from the moment the blood is shed to when it congeals, as indicated by the inversion of the tube.

A more accurate method and one which requires only a drop of blood is the following. The blood is drawn into a capillary glass tube about 4 or 5 inches long. A section of the tube is broken off from time to time. The time elapsing from the moment at which the wound was made to that when fine threads of fibrin appear between the ends of the broken sections of the tube is taken as the coagulation time. The normal coagulation time by this method is about 4 minutes. There are many other methods for determining the coagulation time, e.g., Brodie's, Gibbs', Cannon and Mendenhall's, etc., but all have their defects and the foregoing is probably just as accurate as more elaborate procedures.

Clot retraction time. This is measured by collecting a few cubic centimeters of blood into a test tube. After clotting has occurred the clot is separated from the walls of the tube by means of a fine wire and the tube placed in an incubator set at a temperature of 37°C. The clot of blood retracts to a firm mass, the serum separating out within a couple of hours. In certain types of purpura (thrombocytopenic) the clot remains bulky, soft and friable. In hemophilia, on the contrary, when clotting does occur, the clot usually retracts normally.

THE BLEEDING TIME

The determination of the bleeding time simply consists in pricking the skin and noting the time the drop of blood takes to clot sufficiently in order to close the puncture in the skin and stop the bleeding. The precise moment when bleeding ceases is determined by touching the blood from the tiny wound every few seconds with a piece of filter paper. The moment when the latter ceases to be stained is taken as the end point. The normal

bleeding time is about 2½ minutes.² One might suppose that the bleeding time would be a better gauge of the body's ability to protect itself against hemorrhage than the coagulation time, but the fact that it is normal, as a rule, in hemophilia (see below) shows that this is not so. Actually, there is little relationship between the bleeding time and the coagulation time. The former is prolonged in conditions associated with low platelet counts. It is shortened by the local application or intravenous injection of platelet extracts, by the application of solutions with a low pH (around 5), or by the injection of posterior pituitary extracts. Ordinary hemostatics either have no effect or prolong the bleeding time.)

DISEASES ASSOCIATED WITH ALTERED COAGULABILITY OF THE BLOOD

Hemorrhagic tendencies due to a low prothrombin concentration have been mentioned (p. 90). A fibrinogen defect is a rare cause of bleeding. There may be a congenital lack of this plasma protein, amounting even to its complete absence. It is well to emphasize here that a low serum calcium is never a causative factor in hemorrhagic diseases. In hypoparathyroidism in which the serum calcium may be depressed to less than half the normal value the coagulation time is not lengthened.

Hemophilia

The coagulation time but not the bleeding time as defined above is greatly prolonged in this condition.³ In some cases the blood after removal from the body may show no signs of clotting after an hour or so. On this account a fatal hemorrhage may follow a wound that would be trivial in a normal person. The extraction of a tooth, a slight accident or a minor operation has resulted in death on many occasions. The subjects of this disease

² Ivy and his associates recommend first raising the venous pressure in the arm by constricting it above the point where the skin puncture is to be made. A constricting pressure of about 40 mm. Hg is applied. Tocantins has devised an instrument which makes an incision of approximately uniform length and depth.

³ Not every person with a tendency to bleed can be classed as a hemophilic. True hemophilia answers to the following criteria.

- (a) Males only.
- (b) History showing characteristic type of inheritance.
- (c) Coagulation time of drawn blood, but not the bleeding time, is greatly delayed.
- (d) No reduction in platelets, but these show lessened fragility.
- (e) Quick's test positive.

are known popularly as "bleeders." Hemophilia is transmitted as a sex-linked recessive character. The males are affected but do not transmit the disease; the females, though they transmit the disease do not suffer themselves (law of Nasse (1820)). A father then, who is a "bleeder" does not transmit the disease to his children in a manifest form. His sons are entirely free from any taint but his daughters inherit the disease in a masked or latent form and transmit it to their offspring. Of these the males show the disease, and the daughters again are not "bleeders" but are "carriers" for the next generation. In other words the disease skips a generation. Some of these bleeder families have been traced back for a hundred years or so and cover in some cases 5 generations and hundreds of individuals. The incidence of the disease in these instances followed in general the plan outlined above. It is theoretically possible should a "bleeder" and a "transmitter" marry, for the female as well as the male children to be "bleeders." Such a coincidence must be so very rare that for practical purposes it may be said that true hemophilia never occurs in the female.

The essential defect in hemophilia is a deficiency of thromboplastin due, it is thought, to an abnormal stability of the platelets. The conversion of prothrombin to thrombin is therefore retarded. Quick has devised a test for hemophilia based apparently on the resistance of the platelets to fragmentation. The plasma of a suspected hemophilic is rendered incoagulable by the addition of 0.5 cc. of a 0.1 molar solution of sodium oxalate. The oxalated plasma is divided into two equal portions. One half is centrifuged at 1000, the other at 3000 revolutions per minute. The two samples are then recalcified by the addition of 0.2 cc. of a 0.0125 molar solution of calcium chloride. The portion centrifuged at the higher rate will be found to have a considerably shorter clotting time than that portion centrifuged at the lower rate. The clotting time of normal plasma, on the contrary, is not affected significantly by the speed of centrifugation, both samples clotting at approximately the same time following recalcification. The other factors concerned in the coagulation mechanism appear to be normal. The calcium, prothrombin or fibrinogen is not diminished and heparin has not been shown to be increased. The logical corrective measure in persistent bleeding from this cause, is blood transfusion or the direct application of tissue extract or of healthy blood to the bleeding point. Barnett

and Macfarlane have reported a series of cases in which highly successful results were obtained from the application of snake venom to the wound. A 1 in 10,000 solution of venom of Russell's viper was used.

A bleeding tendency is sometimes seen in women but it differs from true hemophilia in that there is a prolonged bleeding time and the typical family history is absent. Quick's test is negative.

Purpura

This is a term applied to a variety of hemorrhagic states in which spontaneous bleeding occurs beneath the skin, from the mucous membranes or into joints. The subcutaneous hemorrhages appear as small or large purplish spots (*petechiae* and *ecchymoses* respectively) which gradually pass through the color changes characteristic of a bruise. Since purpura is so varied in its characters and occurs in diseased states that are so widely different, it should be considered as a symptom of a disorder of the blood-vascular system rather than as a disease in itself. It occurs in the malignant forms of many acute diseases—smallpox, scarlet fever, diphtheria, streptococcal infections, etc. Subcutaneous and submucous hemorrhages are also features of scurvy, leukemia, certain anemias and of the action of various toxic agents, e.g., snake venoms, drugs and chemicals. In some types of purpura (e.g., infectious and toxic forms) *deterioration of the capillary wall* probably plays the chief rôle—the red cells escaping into the subcutaneous tissues or from the mucous membranes through capillary defects. On the other hand a *great reduction in platelets* appears to be an important if not the essential defect in other types and a condition resembling purpura hemorrhagica (see below) has been induced in animals by the injection of an antibody developed for the destruction of platelets. Nevertheless the experiments of Bedson suggest that reduction of platelets or even their entire absence is not capable alone of inducing purpura. Some injury to the capillary wall must co-exist. This observer also found that splenectomized guinea pigs were highly resistant to the action of the anti-platelet serum. A theory has been advanced which relates the capillary defects to platelet reduction. It is probable that the platelets serve, normally, to protect the capillary wall and, by their deposition upon the endothelium, act as a seal against the escape of red cells through weakened points which are constantly occurring from general wear and tear. The reduction in platelets may result from several causes. There

may be increased destruction of these elements or the normal mechanism of their production may be interfered with, as in aplastic anemia and leukemia.

The coagulation time in purpura is usually within normal limits but the bleeding time is as a rule prolonged. The clot which forms in the blood after it has been shed is said to be softer than the normal and does not contract and express the serum in the usual way.

THE CAPILLARY RESISTANCE TEST. When cutaneous purpuric spots do not occur spontaneously they may be induced in susceptible persons by means of a tourniquet or blood pressure cuff applied to the upper arm so as to obstruct the venous return but not the artery. The obstruction is maintained for 5 minutes. In scurvy and other conditions associated with weakness of the capillary membrane the increased intracapillary pressure so induced results in the formation of small hemorrhagic points (petechiae) beneath the skin of the forearm. A more precise method consists of the application to the skin (usually of the forearm just below the antecubital fossa) of a small suction cup and determining the minimum negative pressure which, when applied for one minute, is required to produce petechiae. In health this lies between -200 and -300 mm. Hg. A minimum effective pressure less than -200 mm. Hg is abnormal.

Purpura hemorrhagica or Werlhof's disease (thrombocytopenic purpura) is associated with a great reduction in the platelet count. They may be almost absent from the circulation. Splenectomy is followed by an increase in platelets and frequently effects a cure. Recently snake venom has been successfully employed in the treatment of this disease. The observations of Troland and Lee point to the spleen in this disease as the source of a toxic material having a destructive action upon platelets. An acetone extract of the spleens of patients suffering from thrombocytopenic purpura upon injection into rabbits was followed by a prolonged fall (from 640,000 to 20,000 in 24 hours) in the platelet count. They have given the name *thrombocytopen* to the unidentified active principle in the extracts. Extracts prepared in the same way from normal spleens were without effect upon the platelet count. An abnormal number of megakaryocytes in the bone marrow especially of younger forms has been reported in purpura hemorrhagica and it is suggested that the failure of these to produce platelets is the fundamental fault.

In one form of purpura—*purpura fulminans*—the hemorrhages are exceptionally severe and the subcutaneous extravasations often extensive. Death may occur within a few days from loss of blood. In this state there is undoubtedly an affection of the capillary endothelium as well as reduction in the number of

thrombocytes. Purpuric manifestations may occur with more or less severe symptoms of gastro-intestinal irritation—*Henoch's purpura*—or in others bleeding into the joints (*Schonlein's disease*) is a prominent feature. In either of these forms the purpuric spots may occur in association with urticarial wheals or more generalized edematous swellings of the subcutaneous tissues. Capillary damage is probably either the essential or a contributory factor in these conditions.

Calcium is commonly employed in the treatment of the various types of purpura and appears to reduce the hemorrhagic tendency but the manner in which the effect is brought about is obscure; it is not through increasing the coagulability of the blood.

INTRAVASCULAR CLOTTING—THROMBOSIS

Coagulation within the vessels may be brought about experimentally: (a) By the injection of thrombin into the blood stream (see p. 92). Repeated injections of small amounts of thrombin cause the blood, after the first immediate increase of coagulability, to become for a few hours less coagulable than normal (negative phase). This is due apparently to the compensatory production of an antithrombin. No *permanent* reduction in coagulability can however be produced by repeated injections of thrombin over a period of several weeks. (b) By the rapid injection of a tissue extract (thromboplastin) particularly of the lung, thymus or lymph glands. This effect can be annulled by heparin. The repeated injection of *small* amounts of tissue extract has the reverse effect—decreased coagulability. This was shown by Mellanby and later by Mills and his associates to be the result of the gradual deposition of fibrin upon the vascular walls. The blood failed to clot simply because it had been depleted of fibrinogen. (c) By injury to the vessel wall either by chemical, mechanical or infective agencies, a roughened surface being thereby exposed to the blood stream. Thromboplastin is also liberated from the injured vascular wall.

Intravascular clotting involving areas of varying extent may occur in the human body from several causes. It is very doubtful whether this ever occurs as a direct result of an increase in any of those elements of the clotting mechanism normally present in the circulating blood, i.e., prothrombin, calcium or fibrinogen—or of a reduction in anti-thrombin (heparin). The increased liberation of thromboplastin which must result when tissue cells, whether of the blood vessels or other structures, are injured is probably, as suggested above, a factor under certain circumstances. The effect of this, however, is believed to be confined to the region in the immediate neighborhood of the

injury. It is unlikely that the liberated thromboplastin is capable of exerting an effect upon the blood as a whole, and cause clotting at a remote point in the vascular system.

The formation of a compact and solid mass of blood in a vessel (vein or artery) which partially or completely closes its lumen is spoken of as *thrombosis*. The plug itself is termed a *thrombus*. A thrombus may be formed simply by the clotting of the blood in the usual way, as occurs in an injured vessel. On the other hand the cellular elements of the blood may form a solid mass within a vessel and block its lumen independently of the clotting process. This occurs sometimes in the smaller vessels when the red cells become agglutinated into large clumps (agglutinative thrombus) as after the transfusion of incompatible blood. Once the vessel has become plugged in this way a true clot of course will form in the stagnant blood column. Owing to the slower blood flow in the veins it is in these vessels that thrombosis usually occurs.

When a thrombus, or a portion of it, becomes detached and carried away in the blood stream to become impacted in an artery at some remote point in the circulation, it is spoken of as an *embolus*. When arising from a venous thrombus the embolus is likely to lodge in a vessel of the lung. If formed in the left heart it may plug a cerebral vessel. The main vessel leading to a circumscribed area may become obstructed and the anastomosing channels be insufficient to maintain the nourishment of the tissue. The isolation of an area in this way by the obliteration of its artery is spoken of as *infarction*, and the necrotic area as an *infarct*.

Causes of thrombosis

The causes of thrombosis in the human subject may be grouped under the following heads.

(1) **INJURY TO THE VESSEL.** Complete mechanical obstruction of the circulation as by a ligature or pressure upon a vessel from without does not alone cause thrombosis. The latter is usually associated with some injury to the inner wall of the vessel; unless this occurs the blood may remain fluid for a considerable time.⁴ A thrombus, often very small in size, may form later

⁴ The importance of a smooth endothelial lining and the fact that stoppage of the blood stream alone does not necessarily cause clotting is demonstrated in the classical experiment of the "living test tube." If a section of the jugular vein of an animal, e.g., the horse, be isolated between ligatures and carefully removed with its contained blood, this will not clot for a long period, not until changes occur in the lining of the vessel wall and the necessary thrombokinase is thereby provided.

merely as the result of the slowing of the stream, the formation of eddies in the blind pocket and the deposition of platelets. Sometimes practically no thrombus is formed and the lumen of the vessel is obliterated by proliferation of the cells of the lining membrane.

(2) **AGGLUTINATION OF CORPUSCLES** (agglutinative thrombus).

(3) **TOXIC THROMBOSIS.** Certain chemical poisons, e.g., arsenical compounds, mercury, potassium chlorate, etc., may cause intravascular clotting. Poisonous mushrooms, certain snake venoms, as well as toxins formed within the body, as in eclampsia; or extensive burns, may induce thrombosis. The manner in which these various agencies act, whether by injury to the vessel wall, disintegration of blood elements, or through their effects upon some phase of the clotting process is obscure.

(4) **INFECTION BY MICROÖRGANISMS.** This is a common cause. The smooth endothelial lining is destroyed or roughened by the inflammatory process, thrombokinase is liberated from the injured tissues and disintegrated platelets. The latter probably also liberate prothrombin. Some degree of thrombosis is always associated with acute inflammatory processes of septic origin. The thrombosis may be strictly localized to the smaller vessels at the site of the infection, or may extend into larger venous trunks, and is then due to the spread of the infection along the vein walls (phlebitis). The thrombosis of the femoral vein during the puerperium or of a cerebral sinus following mastoid disease are typical examples of infective thrombosis.

(5) **SLOWING OF THE BLOOD STREAM—SPONTANEOUS OR POST-OPERATIVE THROMBOSIS. PULMONARY EMBOLISM.** Spontaneous thrombosis may occur under a variety of conditions, and in practically any vein in the body. Thrombosis, particularly of the veins of the lower limbs, not infrequently follows operations upon the abdominal or pelvic organs. When it occurs under these circumstances it is always a cause of anxiety to the surgeon because of the danger of the clot becoming detached and carried to the lung where it may block a branch of the pulmonary artery (pulmonary embolus). Infection is frequently blamed, but in most cases no evidence for this can be found. Also, the point where the thrombus forms—usually in the femoral vein—lies at a distance from the field of operation and is separated from it by a considerable extent of healthy tissue. This precludes direct spread either of infection or of thrombus formation from the site of the wounded tissues.⁵ Furthermore, thrombosis

⁵ The left femoral vein is more frequently involved than the right, and this has been explained by the greater resistance which the left common iliac vein offers to the blood flow in consequence of certain anatomical peculiarities. The left common iliac vein is longer and more oblique than the right and passes beneath the right common iliac artery. An adhesive band also in a certain proportion of cases passes between the anterior and posterior walls of the left vein. The vein of this side also, it is thought, suffers from pressure by a distended rectum or sigmoid flexure.

of this type is much more common now than in the past when aseptic technique was less perfect. We must therefore look elsewhere for the cause of post-operative thrombosis. The possible mechanisms concerned may be grouped under the following headings.

(a) *Slowing of the blood stream* as a result of enfeebled heart action, prolonged confinement to bed, debilitating diseases associated with a low metabolic rate and hypotension, or immobility of the limbs, seems to be an important factor in causation (p. 147).

(b) *Blood changes.* The platelets are increased after operations, and these elements show a greater tendency than is normal to clump together. The greater stickiness is due, according to Wright, to newly formed cells discharged from the bone marrow. The fibrinogen also is increased and, as a result of this, the rate of sedimentation of the corpuscles is hastened (p. 50).

(c) *The coagulation time* is shortened for the first few days after operation but it is doubtful whether an altered relationship between the different factors concerned in the clotting mechanism itself is really of importance in the production of post-operative thrombosis. At first sight the liberation of thromboplastin from the damaged tissues would seem to be the obvious cause of the thrombosis. Yet if this were responsible one would expect that thromboses would occur immediately following operation and not as is actually the case a week or ten days later. Moreover, thrombi composed of masses of platelets have been induced in animals whose blood had been rendered incoagulable, and post-operative thrombosis may occur in subjects whose blood shows a clotting time within the normal range.

Aschoff has made an experimental study of post-operative thrombosis and gives an interesting and logical explanation of the processes involved. He states that when the vein is completely obstructed, as is usual, the thrombus has a white portion or head which is directed proximally and a dark red portion or tail. If the flow of blood is not completely blocked the thrombus consists of the white portion alone. A minute examination reveals a framework of ribs or beams extending from the wall of the vein and traversing the entire substance of the white thrombus. The ribs are made up chiefly of massed platelets covered with a layer of leucocytes. *There is little or no sign of fibrin or of red cells so that this white plug is not a clot in the ordinary sense.* The longer red portion or tail of the thrombus extends distally for a variable distance along the vessel and is made up of all the elements of the blood in their normal proportions. Fibrin threads are plentiful. This portion is evidently formed by the coagulation of the blood en masse, as it is finally brought to a standstill by the obstruction of the vessel by the white thrombus, which is formed *while the blood is flowing*. The arrangement of the platelets to form the framework of the head of the thrombus is explained simply by the slowing of the blood current. The ribs or beams formed of accumulated platelets commence as low ridges upon the inner surface of the vein wall.

The mode of deposition is compared to the manner in which sand, though kept in suspension in a rapid stream, is deposited in a ribbed pattern upon the sea shore or at a river's mouth where the current is slowed. Though the flow of blood in the veins is continuous it is not absolutely even; eddies occur in the venous current and even slight muscular movement causes a certain irregular wave-like motion of the blood column which accounts for the deposition of the platelets, not in a continuous even layer but, in ripples. Also, owing to their lower specific gravity the platelets leave the axis or core of the stream and separating from the other blood elements come to occupy the more slowly moving zone next the vessel wall. Finally, it is the reduction of the velocity in this outer zone of the current to a certain critical level that causes the platelets to settle upon the vascular walls. The ribs or ridges increase in height by the aggregation of fresh platelet masses, and secondary ridges are later formed upon the primary ones until at last the fabric extends like a coral growth into the axis of the stream. The blood flows sluggishly through the sponge-like texture of the developing white thrombus, and by its pressure warps the beams in the direction of its flow. The leucocytes also because they have a lower specific gravity than the red cells, separate from these and move in the outer currents of the many streams into which the original blood column has been now divided. They cling to, and finally come to rest upon the walls of the new-formed channels, and ultimately filling them cause complete blockage of the vessel.

Between the white and red portions of the thrombus an intermediate portion or neck can often be seen. Here masses of red cells are also held in the white net though there is still a disproportionately large quantity of the white elements. Evidently the red cells had been caught in the mesh at the moment that the spaces in the forward part of the white thrombus had become filled with white cells and so brought the circulation to a standstill. The disposition in this way of the colored and colorless cells gives a stratified appearance to this intermediate part of the thrombus.

In the auricles during auricular fibrillation, in the slowing of the stream caused by a local dilatation of the blood channels, e.g., in an aneurysm or varicose vein, and wherever eddies are produced, a white thrombus either with or without a covering of clotted blood, is likely to form as a result of platelet deposition. The formation of such a thrombus in the femoral vein would perhaps be of little consequence if there were no danger of the plug of blood becoming detached, since the circulation would be carried on through collateral channels—or the thrombus itself would probably in time undergo canalization with consequent re-establishment of the current in the vessel. The grave danger as already mentioned is the transportation of the clot to the lungs and the obstruction of one or both branches of the pulmonary artery. Emboli found in this situation after death have the structure of a thrombus as described above, and are of a size which can be ac-

counted for only by their formation in a vessel such as the femoral. These facts indicate that a cramped or dependent position of the limbs, complete immobility or any other circumstances that will enhance or cause retardation of the circulation in the veins of these parts, quite apart from infection or vessel injury, will be conducive to thrombus formation.

The observations of Sandison are pertinent to the question of thrombus formation. Examining the blood flow through the capillaries of the rabbit's ear by the transparent chamber method, he observed thrombi in the process of formation. When the blood flow was retarded platelets were seen to cling to the wall of the capillary or venule. By the deposition of successive layers, a white thrombus was formed which as it grew extended a considerable way along the blood channels. A small proportion of leucocytes were included in the mass, but no erythrocytes.

Though slowing of the venous flow is probably the most important factor in the production of post-operative thrombosis, alterations in the blood itself which follow tissue injury, namely, the increase in the

number of platelets and their tendency to clump together, the rise in fibrinogen concentration and the effect of this upon the sinking rate of the cells, no doubt encourage the formation of the white thrombus. Anhydremia by increasing the viscosity of the blood also favors its occurrence.

The following are the chief measures employed in attempts to prevent post-operative thrombosis.

(1) Early movement of the limbs, to favor the venous flow.

(2) Avoidance of any restriction to respiration—which is an important factor in aiding the venous return from the limbs.

(3) Thyroid extract administration, to raise the metabolism and increase the circulation rate.

(4) Plenty of fluids, to prevent dehydration, and a diet composed largely of carbohydrate since the platelet count and the fibrinogen are raised by a high protein diet.

(5) The use of anticoagulants such as heparin by continuous administration (p. 89) and of sodium thiosulphate is in the trial stage.

CHAPTER XIII

THE MECHANISMS REGULATING THE REACTION OF THE BODY FLUIDS

PHYSICO-CHEMICAL PRINCIPLES

THE ELECTROLYTIC DISSOCIATION THEORY

When certain chemical substances such as acetic acid, hydrochloric acid and many others, are dissolved in water a proportion of their molecules—the proportion varies with the particular substance—undergo dissociation into their constituent *ions*. The latter move through the solution in all directions, some collide with one another and recombine, while a corresponding number are produced by the dissociation of other molecules. By the junction of some ions and the separation of others, the balance between undissociated (unionized) and dissociated (ionized) molecules is kept constant. That is, equilibrium is established. Substances whose molecules are dissociated in this way are known as *electrolytes*. An ion is an electrically charged atom or group of atoms and is referred to as a *cation* or an *anion* respectively according to the nature of the charge—positive or negative—which it holds. Cations are denoted by a plus sign or simply by a dot placed above the atomic symbol. The negative ion (anion) is indicated by a minus sign or an oblique dash. Thus HCl dissociates into the ions H^+ and Cl^- ; H_2O itself into H^+ and OH^- into H^+ and HCO_3^- . If an electric current be passed through the solution each ion carries a charge of electricity to one or other electrode, the anions (negative ions) migrating to the positive electrode or anode and the cations (positive ions) to the cathode. The conduction of an electric current through the solution will therefore be influenced by the concentrations of ions in the solution (i.e., upon the degree of dissociation of the particular electrolyte). Solutions of such substances as sodium chloride are good conductors, while solutions of others like cane sugar which undergo little or no dissociation are not much better conductors than pure water.

When (1) the degree of dissociation of an acid or other electrolyte and (2) the total concentration of the acid in the solution are known, then the concentrations of dissociated and undissociated molecules can be calculated. It is found that after equilibrium has been established the product of the concentrations of ions divided by the concentration of the undissociated molecules gives, at a given temperature and for a given electrolyte, a constant value which is known as the *ionization* or *dissociation constant*. This represents the operation of the mass law¹ as applied to the dissocia-

tion of electrolytes. So if HA represents an acid which is dissociated into cations H^+ and anions A^- then K_a represents the dissociation constant of the acid. The brackets enclosing the letters represent molar concentrations. Thus

$$\frac{\text{Dissociated}}{[\text{H}^+] \times [\text{A}^-]} \div \frac{\text{Undissociated}}{[\text{HA}]} = K_a \text{ (Ionization or dissociation constant)}$$

After equilibrium has been reached the velocity at which the molecules HA dissociate into H^+ and A^- is equal to that at which the latter combine to form HA. In this way an equilibrium between dissociated and undissociated molecules is maintained; thus, $HA \rightleftharpoons H^+ + A^-$. For weak electrolytes the degree of dissociation increases with dilution, so that at infinite dilution the dissociation is complete. The greater the degree of dissociation the higher will be the numerator of the equation, and the higher consequently will be the value of the dissociation constant.

HYDROGEN ION AND HYDROXYL ION CONCENTRATIONS

The ionization of acids

If a measured amount of a normal solution of acetic acid be titrated against a normal solution of sodium hydroxide a definite amount of the base will be required for neutralization. If the same quantity of a normal solution of HCl be taken and titrated as before, it will be found that precisely the same amount of base will be required for complete neutralization. From this it might be assumed that the two acids are equally strong. But it is known that at similar concentrations the acid properties of hydrochloric are incomparably greater than those of acetic acid. The former inverts cane sugar more powerfully, it tastes more acid, it has a greater destructive effect upon animal tissues, and it will displace acetic acid from its salts.

Hydrochloric acid is dissociated into hydrogen ions and chlorine ions. To the H-ion it owes its

¹ The mass law states that the velocity of a chemical reaction is proportional to the concentrations of the reacting substances. This law while it holds for dilute

solutions of such weak electrolytes as are present in blood is inaccurate in the case of strong electrolytes in concentrated solutions.

acid properties; it is the hydrogen *ion* concentration and not the total number of hydrogen atoms in its molecule that is responsible for the acid characters of any acid. The greater the degree of dissociation of the acid, the greater is the number of H-ion which it will yield in solution, i.e., the greater will be the H-ion concentration, and the greater consequently will be its acid nature. Thus HCl though it contains only one atom of hydrogen in its molecule undergoes almost complete dissociation and is in consequence a much stronger acid than carbonic (H_2CO_3) whose molecule contains two hydrogen atoms but dissociates to a very small extent into H^+ and HCO_3^- ; carbonic acid dissociates in two stages. Phosphoric is another weak acid which contains three atoms of hydrogen. It dissociates, however, to a greater extent than carbonic acid and in three stages:

The greater the degree of dissociation of an acid the higher will be the value of its dissociation constant. The latter therefore is a true measure of "acid properties." The dissociation constant of a very weak acid such as carbonic is only 0.0000003 (first stage); the first dissociation constant of phosphoric acid is 0.011.

The ionization of bases

The OH ion on the other hand gives to bases in aqueous solution their characteristic properties, and when a base and acid neutralize one another it is the union of the hydrogen ion of the acid with the hydroxyl ion of the base with the formation of a molecule of water that brings about neutralization, thus:

The ionization of a base may therefore be represented by an equation analogous to that given for an acid. Thus:

$$\frac{\text{Dissociated}}{[\text{B}^+] \times [\text{OH}^-]} = K_b$$

Undissociated
[BOH]

If the hydrogen ions are in excess the solution is acid; if the hydroxyl ions are in greater concentration the solution is alkaline.

The ionization of water—The reaction of a solution expressed in terms of hydrogen ion concentration

The dissociation of water may be represented by the equation

$$\frac{[\text{H}^+] \times [\text{OH}^-]}{[\text{H}_2\text{O}]} = K_w$$

Pure water has a definite though very slight conductivity value. The concentration of the molecules that are dissociated into H^+ and OH^- as compared with those undissociated is almost infinitesimal; the concentration of the H^+ and OH^- is so small that their presence produces no measurable decrease in the concentration of the total water molecules. The equation then may be written simply—

$$[\text{H}^+] \times [\text{OH}^-] = K_w$$

K_w , the dissociation constant for water therefore represents the product of these ionic concentrations and amounts to no more than 0.00000000000001.

Expressed more briefly, though perhaps more cryptically the value is 1×10^{-14} . The symbol -14 to the right of the figure 10 is termed the negative exponent or index, and means that in order to express the value in the form of a decimal fraction, as in the preceding paragraph the figure 1 must be placed 14 places to the right of the decimal point. Expressed as a vulgar fraction 10^{-14} would be $\frac{1}{100000000000000}$

Other examples of this system of notation are

$$\begin{aligned}10^{-1} &\text{ means } 0.1 \text{ or } \frac{1}{10} \\ 10^{-2} &\text{ means } 0.01 \text{ or } \frac{1}{100} \\ 10^{-3} &\text{ means } 0.001 \text{ or } \frac{1}{1000} \text{ and so on.}\end{aligned}$$

We already know that the H^+ and OH^- must be present in equal concentration and that the dissociation constant 1×10^{-14} is the product of these concentrations, i.e., the square of either. Therefore the square root of 1×10^{-14} i.e. 1×10^{-7} indicates the concentration either of the H^+ or of the OH^- .

The *actual weight* of ionized water in 1000 cc. (1 liter) of water is therefore

$$\begin{aligned}&1 \times 10^{-7} \text{ grams H ions (atomic weight of} \\ &\quad \text{hydrogen} = 1) \\ &17 \times 10^{-7} \text{ grams OH ions (atomic weight} \\ &\quad \text{of oxygen} = 16) \\ &\hline &\text{Total } 18 \times 10^{-7} \text{ grams ionized H}_2\text{O.}\end{aligned}$$

A solution containing 1 gram of hydrogen ion per liter is known as one having a normal concentration of hydrogen ions. Seventeen grams of OH ions in the same quantity of fluid is known as a normal solution of hydroxyl ions. Water is therefore 10^{-7} normal in both H^+ and OH^- ions. Since both are in equal numbers per unit of fluid, water is neutral in reaction.

If hydrochloric acid be added to water it is dissociated to the extent of over 90 per cent into H^+ and Cl^- . The concentration of H^+ in the water will therefore be greatly increased by the addition of acid. But it has already been seen that the product of the concentration of H^+ and OH^- in water is constant (K_w). This statement applies not only to pure water but to all aqueous solutions. *This is a fundamental fact* and upon it the determinations of the hydrogen ion concentration and the notations used for its expression are based. When therefore the H^+ are increased the OH^- must undergo a reciprocal reduction. If, for instance, the H^+ concentration is increased above its value in pure water, that is from 1×10^{-7} to say 1×10^{-6} (0.0000001 N to 0.000001 N) then the concentration of OH^- must undergo a reduction to 1×10^{-8} in order that the product of these two shall remain the same ($1 \times 10^{-6} \times 1 \times 10^{-8} = 1 \times 10^{-14}$). On the other hand if a base be added to water and the OH^- concentration increased from its value in pure water, i.e., from 1×10^{-7} to, let us say, 1×10^{-6} , the H^+ concentration must undergo a corresponding diminution from 1×10^{-7} to 1×10^{-8} (0.0000001 N to 0.00000001 N). It is clear therefore that all that is required in order to indicate the concentrations of both H^+ and OH^- ions is an expression which denotes the concentration of either one. The concentration of the H^+ has therefore been chosen to express the reaction of a solution. The term "hydrogen ion concentration" is abbreviated to the symbol cH. If the hydrogen ion concentration (cH) is greater than that of pure water the reaction is acid, if less than this value the reaction is alkaline, and if precisely the same the reaction is neutral. Thus:

If cH equals that of pure water i.e. 1×10^{-7} the reaction is neutral.

If cH exceeds that of pure water e.g. from 1×10^{-7} to 1×10^{-1} the reaction is acid.

If cH is less than that of pure water e.g. from 1×10^{-7} to 1×10^{-14} the reaction is alkaline.

The values represent the H^+ concentrations in terms of a normal solution (i.e., one containing 1 gram of ionized hydrogen per liter). No matter how concentrated in a solution the H^+ may be,

some OH^- are always present, and vice versa, with maximum alkalinity there are always present a small number of H^+ .

The symbol pH

The values of the hydrogen ion concentration as indicated above was found inconvenient. When the cH was 1×10^{-6} , 1×10^{-8} etc., the first factor could, for the sake of simplicity, be omitted. The expression then became cH, 10^{-6} , etc. But when the first factor was other than unity, e.g., as in 5×10^{-6} or 1.3×10^{-7} or 4×10^{-8} this obviously could not be done. The writing of such expressions became cumbersome and the hydrogen ion concentrations which they represented were difficult to keep in mind.

Sorensen in 1909 introduced a system of notation by which the negative exponent of the common logarithm (i.e., to the base 10) of the decimal fraction expressing the H-ion concentration, is employed as a positive number. For example the H-ion concentration of serum is 0.0000004 normal. The cH might be expressed either as 4×10^{-8} N, or as $1 \times 10^{-7.40}$ N. The latter expression is simplified by omitting the 10 and replacing the minus sign of the negative exponent by the symbol pH (hydrogen ion exponent). The value 7.40 is derived as follows. The log of the figure in the cH expression above, i.e., 4, is 0.6021 (cf. log tables). This log subtracted from the negative exponent, i.e., 8, gives the required figure 7.40. Similarly a solution 0.0000005 normal in H-ions may be expressed either as cH 5×10^{-8} or as cH $1 \times 10^{-5.3}$. The log of 5 is 0.6990; the pH is, therefore, $6 - 0.6990 = 5.3$.

In order to convert pH into cH the figure for the former is subtracted from the next higher whole number. The antilog of the difference is then obtained from the antilog table. This gives the first figure in the cH expression. The whole number gives the negative exponent of 10. For example, in the last expression given above (pH 5.3) the next higher whole number is 6; $6 - 5.3 = 0.7$. The antilog of 0.7 is 5; so the cH is 5×10^6 .

It must be remembered that a rise or fall in the pH indicates a change in hydrogen ion concentration (cH) in the opposite direction. Thus a pH of 5.00 indicates a higher acidity than a pH of 6.00. pH 7.00 of course indicates neutrality. Attention should be drawn to another point that is not quite so obvious, namely that a solution of a pH 5.00 is more acid not simply by a sixth than a solution of pH 6.00, but is in fact ten times more acid.

A pH of 3.00 represents an acidity 1000 times greater than a pH of 6.00. Similarly a solution of pH 11.00 is 1000 times more alkaline than one of pH 8.00. Recalling the decimal fraction which these figures represent will make this clear. Thus pH 5.00 = 0.00001 normal and pH 6.00 = 0.000001 normal.

BUFFERS

These are substances which when present in a solution maintain the latter at a relatively constant pH when an acid or alkali is added to it. That is, a buffer has the power to "soak up" or "tampon" the acid or base; it takes up the shock so to speak of the strong acid or base, hence the term buffer. A buffer or buffer system consists

The hydrogen ion concentration of the solution is equal to the product of the dissociation constant of the acid (K) and the ratio of the buffer pair. Thus:

Hydrogen ion concentration [H] = $K \frac{[HA]}{[BA]}$

In order to express the H ion concentration in terms of pH, the value for K is converted by means of logarithms to the corresponding pK figure. The equation then becomes:

$pH = pK + \log \frac{[BA]}{[HA]}$

This is known as the Henderson-Hasselbalch equation.

TABLE 12

HCl ADDED	$\frac{H_2CO_3}{NaHCO_3}$	[H]	[OH]	RELATIVE ACIDITY	RELATIVE ALKALINITY
grams

320	—	0.00045	0.00000000022	450	0.0022
330	—	0.0027	0.000000000037	2700	0.00037

of two parts—a weak acid and one of the salts of that acid. Acetic acid and sodium acetate; carbonic acid and sodium bicarbonate; phosphoric acid and sodium phosphate, are a few examples of such buffer pairs. Solutions of buffers are used in physiological experiments when for any reason it is desired to maintain the fluid medium at a constant hydrogen ion concentration, as for example in the study of the action of ferments.

The hydrogen ion concentration of a buffer solution is proportional to the ratio of the concentration of the free acid to the concentration of acid bound with alkali. The ratio of the buffer pair may be expressed as follows:

$$\frac{\text{Concentration of free acid}}{\text{Concentration of bound acid}} = \frac{[HA]}{[BA]}$$

The effect of a buffer in preventing changes in reaction of a solution when acid is added may be illustrated by an example given by L. J. Henderson (table 12).

One hundred liters of a 1 per cent solution of sodium bicarbonate is made up and kept in contact with an unlimited atmosphere containing 0.1 per cent of carbon dioxide. Time is allowed for the solution to absorb CO₂ and for equilibrium to be established between the pressure of gas in the atmosphere and that in the fluid. The temperature is kept constant at 17°C. The solution to start with is slightly alkaline. Hydrochloric acid is added in successive amounts up to 330 grams. It may be seen from the accompanying table that the reaction of the solution is practically neutral after as much as 150 grams of HCl have been added. Even after the addition of 250 grams the H-ion concentration is no more than 2.6 times that

of a neutral solution. It is not until the bicarbonate has been completely used up that the acid exerts any great effect. The ratio $\frac{H_2CO_3}{NaHCO_3}$ remains practically unchanged until some 50 grams of HCl have been added.

The reaction may be expressed as follows:

In this reaction three things have occurred.

(1) The very strong acid, hydrochloric, has disappeared, the very weak acid, carbonic, having taken its place.

(2) The weak carbonic acid is volatile and is quickly got rid of by diffusion into the atmosphere. This continues until equilibrium between the pressure of gas in the atmosphere and that in the solution has been re-established.

(3) The bicarbonate has served as a reserve of base which has soaked up or buffered the added acid. The bicarbonate has of course been reduced and finally completely used up in the process.

THE DONNAN THEORY OF MEMBRANE EQUILIBRIUM

The Donnan effect is a state of ionic equilibrium set up between two sides of a membrane by the presence in a solution of electrolytes of an ion (such as protein) to which the membrane is impermeable. It is explained best by an illustrative example. Let two electrolytes, Na^+Cl^- and Na^+P^- , be separated by a membrane which is permeable to the ions Na^+ and Cl^- but impermeable to P^- . Thus,

When equilibrium has become established the product of the concentrations of the diffusible ions (Na^+ and Cl^-) on one side of the membrane equals the product of the concentration of these ions on the other side.

$$\begin{array}{c} [Na^+] \times [Cl^-] = [Na^+] \times [Cl^-] \\ | \\ [P^-] \end{array}$$

Also on either side of the membrane the total concentration of anions (whether diffusible or non-diffusible) is equal to the concentration of cations, for there is electrical neutrality.

$$[Na^+] = [P^-] + [Cl^-] \quad | \quad [Na^+] = [Cl^-]$$

Since the anion P^- is non-diffusible it follows that the diffusible ions Na^+ and Cl^- must be unequally distributed on the two sides of the membrane. In other words, the non-diffusible ion hinders through electrostatic attraction the free diffusion of the oppositely charged Na^+ ions. The concentration of the Cl^- ion is therefore less and that of the Na^+ ion greater on the side occupied by the non-diffusible ion, thus:

$$\begin{array}{c} | \\ [Cl^-] < [Cl^-] \\ | \\ [Na^+] > [Na^+] \\ | \\ [P^-] \end{array}$$

The ratio of the Na^+ concentrations on the two sides of the membrane (which may conveniently be styled *right* and *left*) is the same as, but reciprocal to, the ratio of the Cl^- concentrations. Thus:

$$\frac{[Na^+ \text{ left}]}{[Na^+ \text{ right}]} = \frac{[Cl^- \text{ right}]}{[Cl^- \text{ left}]}$$

A potential difference is created between the solutions on the two sides of the membrane which is proportional to the logarithm of this ratio. When the ratio is 1:10 the potential difference at 19°C. amounts to 58 millivolts. The state of ionic equilibrium may be represented graphically, thus:

Numbers indicate concentrations in arbitrary units

The Donnan equilibrium is responsible for many physico-chemical effects of the utmost physiological importance, e.g., a difference of pH on two sides of a cell membrane across which H ions can diffuse, differences of electrical potential between

two sides of a membrane and differences in osmotic pressure between the interior of a cell and the extracellular fluids. (See also p. 340.)

THE REGULATION OF THE ACID-BASE EQUILIBRIUM OF THE BLOOD

Acids such as phosphoric, sulphuric and hydrochloric, carbonic and lactic as well as certain organic acids are continually being formed in the processes of metabolism. In diseased conditions, e.g., diabetes, acids such as β -hydroxybutyric and aceto-acetic acids are produced in excessive amounts. Yet in health the reaction of the blood remains remarkably constant at about pH 7.4, and even in disease may show little or no variation from the normal, for the adjusting mechanisms which are called into play to neutralize and remove excess acid perform their duties with extraordinary efficiency.

The reaction of the blood is protected by three lines of defense.

- (1) The buffer systems of the blood
- (2) Excretion of carbon dioxide by the lung
- (3) Excretion of fixed acids by the kidney

The intestinal mucosa also assists to some extent in the removal of acid, particularly of a part of the phosphoric. The rôle played by the kidneys in the regulation of the acid-base balance is considered in chapter XXXVI.

THE BUFFER SYSTEMS OF THE BLOOD may now be enumerated.

I. In the plasma (primary buffers):

- (1) Carbonic acid (free acid) and acid bound as sodium bicarbonate. Ratio 1 to 20.

- (2) The acid and alkaline phosphates of sodium. Ratio 1 to 5.

NaH_2PO_4 may be regarded as a weak acid and Na_2HPO_4 as the salt of the buffer pair.

- (3) Plasma proteins which at the reaction of the blood behave as acids and so combine with base (p. 540).

II. In the corpuscles (secondary buffers). It is to be remembered that whole blood consists of two liquid phases separated from one another by the membrane of the corpuscles. Different materials in different concentrations exist within the red cell and in the plasma. The corpuscles as well as the plasma contain important buffers and an interchange of water, anions and H^+ occurs between the two across the membrane. The corpuscular membrane, on the other hand, is impermeable to the cations Na and K, and to the colloidal anions, hemoglobin and plasma protein. The buffers of the red cells are:

(1) Oxyhemoglobin and reduced hemoglobin act each as a weak acid of a buffer pair of which the potassium salt of the pigment acts as the other half. Thus:

and

- (2) The potassium salts of phosphoric acid:

The reactions by which acids are buffered in the blood may now be considered in more detail. They may be grouped under the following heads:

(1) *Fixed acids* formed during metabolism, e.g., lactic, sulphuric, phosphoric, etc., are buffered by the bicarbonate in a way analogous to that already described on page 000. Taking lactic acid (HL) as a type the reaction may be expressed by the following equation:

The comparatively strong fixed acid is thus replaced by a neutral salt. Phosphates, sulphates, lactates, etc., are excreted in the urine; lactic acid is also removed to a large extent through its conversion to glycogen in the liver and muscles. Carbonic acid is removed through the diffusion of CO_2 into the alveolar air. The great value of bicarbonate in maintaining neutrality of the body fluids is not due so much to its true buffering action, i.e., to the replacement of a strong by a weak acid but to the fact that the latter is volatile and can be eliminated by the lungs.

C—A = carbonic anhydrase

Some of the fixed acid also reacts with the alkaline phosphate with the production of a salt of the acid and a greater proportion of acid phosphate.

The ratio $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ is readjusted by the excretion of the excess acid phosphate in the urine. The phosphate mechanism for removal of excess acid from the body is much less efficient however than in the bicarbonate system, for the reasons that (a) the excretion by the kidney is

relatively slow, and (b) base is lost from the body in combination with the acid. Plasma protein also yields base to neutralize fixed acids.

(2) *Carbonic acid* which as a product of tissue activity is produced in much greater quantities (800 to 900 grams daily) than any other acid, is buffered mainly by base released from hemoglobin. When carbon dioxide enters the blood the sodium bicarbonate of the plasma increases. The increase occurs to a much less extent if plasma separated from the red cells is exposed in the same way to a high tension of CO_2 . The rise in the sodium bicarbonate of whole blood is the result of interchanges between corpuscles and plasma.

It was thought at one time (Zunz) that the rise in plasma bicarbonate was due to the passage of base from the corpuscles into the plasma. It was shown by Gürber and by Hamberger, however, that the rise of bicarbonate was accompanied by a reduction in chloride. It was concluded that chloride derived from the NaCl of the plasma diffused into the red cell and the base thereby released combined with carbonic acid to form bicarbonate. This mechanism is referred to as the "*chloride shift*." The interchanges between the corpuscles and plasma are believed to occur as follows. As the blood passes from the arterial to the venous side CO_2 is absorbed and diffuses into the red cell. Herein, through the action of an enzyme—*carbonic anhydrase*—, it is converted to carbonic acid (H_2CO_3). The oxyhemoglobin becomes at the same time reduced. Reduced hemoglobin is a much weaker acid than oxyhemoglobin and so gives up its alkali to the carbonic acid (see also p. 338). Bicarbonate (KHCO_3) and HHb are formed. The base which previously had been bound to the non-diffusible hemoglobin is now bound as bicarbonate. The concentration of bicarbonate ions (HCO_3^-) in the cells is thereby raised above that in the plasma and, as a result, this anion diffuses across the corpuscular membrane. Since the cations cannot diffuse, the ionic equilibrium between the plasma and the interior of the cell will tend to become disturbed. The balance is adjusted by the diffusion of Cl^- ions from the plasma into the corpuscle (Donnan effect) where they combine with base. The HCO_3^- ions which leave the cells combine with the sodium released from chloride to form plasma bicarbonate. (See schema below.)

The exchanges just described increase the concentration of osmotically active substances within

the cells; water therefore passes from plasma to corpuscle, which, as a result increases in volume. Though described in steps, the reactions actually occur simultaneously; in the lungs, where CO_2 leaves the blood, and hemoglobin becomes a much stronger acid as a result of oxygenation, they are reversed. The alkali is released from its combination with chloride and recombines with hemoglobin. The chloride passes out of the cell. The base furnished by hemoglobin thus serves as the chief means by which CO_2 is carried from the tissues to the lungs.

Carbonic acid is also buffered to a minor extent in the plasma through the protein and phosphate buffer systems. The plasma protein yields base and more free (acid) protein is produced. The alkaline phosphate is converted to the acid phosphate with a consequent fall in the $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$ ratio.

It is evident from the foregoing description of the interchanges between the corpuscles and the plasma that whole blood as compared with plasma possesses a much greater power to buffer CO_2 . For this reason plasma separated from the red cells without precautions to prevent the escape of CO_2 is called "separated plasma" to distinguish it from plasma of whole blood, i.e., plasma in contact with the red cells. Only when precautions have been taken to prevent the escape of CO_2 during the separation of plasma from the cells will the separated plasma have the same reaction and amount of bicarbonate as existed when it was in the body. Only then will the equilibrium between cells and plasma be maintained unchanged. Such plasma is therefore referred to as "true plasma" (see also p. 339).

ALKALI RESERVE—ACIDOSIS AND ALKALOSIS THE ALKALI RESERVE

This term was brought into use by Van Slyke and Cullen to denote the amount of base in the blood which is available for the neutralization of fixed acids, e.g., lactic, hydrochloric, etc. When CO_2 enters the blood, base is liberated in the manner already described and bicarbonate, NaHCO_3 , is formed in the plasma. The plasma bicarbonate then is a measure of the base left over after all acids stronger than H_2CO_3 have been neutralized and thus indicates the reserve of alkali readily available for the neutralization of such acids. The quantity of plasma bicarbonate therefore gives indirectly a measure of the extent of the production of fixed acids in the body. For if acid production be increased the bicarbonate

becomes reduced, its base being given up for the neutralization of the stronger acids. The term alkali reserve, it should be emphasized, refers only to base bound as bicarbonate and not to the total base of the blood. A large quantity of base, Na, K, Mg and Ca is already bound as salts of fixed acids, chiefly sodium chloride, which the weak acid H_2CO_3 is unable to displace (fig. 30). Though changes in the alkali reserve may result from alterations in the body's store of total base, they also occur quite independently of any such change, i.e., simply from variations in the distribution of base between carbonic acid and fixed acids.

FIG. 30. Diagram illustrating normal acid-base balance (modified from Gamble, Ross and Tisdall).

It is also important to remember that the term alkali reserve refers to the *absolute* quantity of bound CO_2 in the plasma and has no reference to the ratio between this value and the quantity of the free CO_2 . Upon this ratio— $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ —the pH of the plasma depends. The plasma bicarbonate may therefore be greatly depleted, yet if the free carbonic acid be reduced to a corresponding extent and the normal ratio of 1:20 thereby maintained, the hydrogen ion concentration will show no appreciable change. Large quantities of acid may be formed in the body yet such is the store of bicarbonate that these, as in the case of the example given on page 102, are taken care of and not until extreme depletion of the bicarbonate

buffer occurs does any great change in blood reaction result.

Rapid adjustments of the ratio $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ are brought about through the exquisite sensitivity of the respiratory center to changes in pH, and to the chloride shift mechanism. The slightest reduction in plasma bicarbonate through its decomposition by acid is met by increased pulmonary ventilation and an equivalent reduction in the numerator of the above expression, i.e., by the elimination of CO_2 by the lungs. Low arterial and alveolar CO_2 tensions are therefore associated with a low alkali reserve.

On the other hand, when excess CO_2 is contained in the blood a compensatory increase in bicarbonate results (chloride shift). So high arterial and alveolar CO_2 tensions are associated with a high alkali reserve.

When excessive amounts of CO_2 are removed from the body (e.g., by forced breathing) a movement of chloride and bicarbonate ions occurs in the reverse direction; the plasma bicarbonate is reduced.

Measurement of the alkali reserve

The alkali reserve is measured by exposing a sample of plasma to an atmosphere of carbon dioxide under conditions similar to those existing in the body, and determining the volumes of gas which are combined as bicarbonate. This is spoken of as the *carbon dioxide combining power*, or the *carbon dioxide capacity* of the plasma. The determination is made as follows. Blood (15 cc.) is drawn from a vein into a syringe containing oxalate to prevent coagulation. Venous stasis, which would cause the accumulation of carbon dioxide and so increase the plasma bicarbonate through the chloride shift mechanism (p. 106) is avoided. The blood is then centrifuged under a layer of paraffin oil which prevents the escape of carbon dioxide, and so a reduction in plasma bicarbonate. After centrifuging the plasma is pipetted off, placed in a saturating vessel and equilibrated with air containing 5.5 per cent carbon dioxide, i.e., the percentage of carbon dioxide in normal alveolar air (tension 40 mm. Hg). The observer's own alveolar air is usually employed. He expires as deeply as possible after an ordinary inspiration into the saturator, through a bottle filled with glass beads; these condense the moisture from the breath, which would otherwise dilute the plasma sample. The saturator is turned end over end for a couple of minutes; the plasma is thus spread over the interior of the vessel in a thin film. After equilibration a measured amount of the plasma (3 cc.) is introduced into a Van Slyke gas apparatus (fig. 31). The CO_2 is then liberated by the action of an acid in the presence of a vacuum, and measured. The result gives the total carbon dioxide

content of the plasma. In order to obtain the quantity combined as bicarbonate the value for the dissolved carbon dioxide, obtained by calculation from the absorption coefficient of carbon dioxide, and the tension of the gas (40 mm. Hg) at which the sample was equilibrated (p. 338), is subtracted (p. 111). The normal values for the carbon dioxide combining power of plasma as so determined range from 53 to 75 volumes

and 75 volumes CO_2 per cent. The free CO_2 being one-twentieth of this, amounts therefore to from about 2.5 to 3.5 volumes per cent.

In disease the pH of the blood, unless in the terminal stage, e.g., diabetic coma, never becomes actually acid, i.e., reaches a pH below 7.0, and as just stated, a reduction in the alkali reserve may occur with little or no change in blood reaction. The limits of pH compatible with life are probably not higher or lower respectively than 7.8 and 6.8. A pH of the latter value has been observed in a case of diabetic coma which ultimately recovered under insulin treatment. The pH of venous blood during rest is lower by 0.02 than that of arterial blood. The red cells are more acid than the plasma by 0.08 to 0.14 pH.

ACIDOSIS AND ALKALOSIS—DEFINITIONS

Few terms in physiology have caused more confusion than these. "Acidosis" has been used with at least two different meanings. The term was originally introduced by Naunyn to denote the production in the body of the abnormal acid metabolites, β -hydroxybutyric and aceto-acetic acids.

The term was used later by Van Slyke and Cullen to mean simply a decrease in the alkali reserve (plasma bicarbonate) below the normal level. This is the sense in which the term has been usually employed. Since the bicarbonate represents the base in the blood which is left over after the non-volatile acids have been neutralized, a reduction in alkali reserve indicates frequently—though not necessarily—that an excess of fixed acids are being produced or retained in the body. We have seen how very efficient the compensatory mechanisms are in keeping the pH constant, and that an acidosis either in the sense of a reduction in alkali reserve or of an increased acid production may or may not be associated with a depression of the pH (reduced alkalinity). We also know that the term acidosis cannot mean any *real* acidity of the blood—a pH below 7.00—for this is incompatible with life, and only occurs when the alkali reserve is very greatly reduced and the bicarbonate buffer ratio cannot be maintained anywhere near the normal value. *Alkalosis* carries the corresponding meaning of an increased alkali reserve. This may or may not be associated with a rise in blood pH (i.e., increased alkalinity).

Van Slyke in a later paper recognizes nine possible acid-base states, one normal, and eight abnormal (fig. 32). He avoids the terms acidosis

FIG. 31. Left hand figure (Van Slyke), volumetric blood gas apparatus; right hand figure apparatus for equilibrating plasma with alveolar air (modified from Peters and Van Slyke).

per cent. A reduction below 50 volumes or so would therefore constitute "acidosis"; above 75 volumes, "alkalosis."

THE NORMAL ACID-BASE BALANCE AND ITS VARIATIONS

The pH of the blood in health varies between 7.3 and 7.45. The normal value for the plasma bicarbonate of venous blood ranges between 53

and alkalosis, using the more precise designations, alkali deficit or CO_2 excess, and alkali excess or CO_2 deficit, respectively. In any one of these, the ratio $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ may be either increased or diminished, with a consequent elevation or depression of pH; the acid-base condition is then said to be *uncompensated*. On the other hand, when adjustments occur to maintain the ratio at the normal value the condition is said to be *compensated*.

Uncompensated alkali excess. In this condition the $[\text{NaHCO}_3]$ is increased without a proportionate rise in

fore normal. A disturbance of this nature will result from conditions which cause (1) but of less severe degree (area 4).

Compensated CO_2 excess. $[\text{H}_2\text{CO}_3]$ increased but accompanied by a proportional rise in $[\text{NaHCO}_3]$; pH is normal. This state occurs in conditions in which there is retention of CO_2 , e.g., emphysema (area 4).

Normal acid-base balance. $[\text{H}_2\text{CO}_3]$, $[\text{NaHCO}_3]$ and pH are normal (area 5).

Compensated alkali deficit. $[\text{NaHCO}_3]$ is reduced and $[\text{H}_2\text{CO}_3]$ diminished proportionately; pH normal. The condition results from the abnormal production of fixed acids as in diabetes; acid retention as in nephritis; or

FIG. 32. Normal and abnormal variations of the $[\text{HCO}_3^-]$, $[\text{H}_2\text{CO}_3]$, CO_2 tension, and pH in oxygenated human whole blood drawn from resting subjects at sea-level.

The curved lines are the CO_2 dissociation curves (p. 338) of reduced (upper curve) and oxygenated blood (lower curve). The straight slanting lines indicate different $\text{NaHCO}_3/\text{H}_2\text{CO}_3$ ratios, the pH at each ratio having been calculated from the Henderson-Hasselbalch equation (p. 102). The CO_2 present as bicarbonate at any point is obtained by subtracting from the total CO_2 the relatively small amount present as H_2CO_3 , indicated by the line near the bottom of the chart. The ratio, and so the pH, is the same at all points along a given line. Thus, the intersection of the CO_2 dissociation curves by these so-called isohydronic lines marks off nine areas corresponding to the acid-base states described above (after Van Slyke).

$[\text{H}_2\text{CO}_3]$. The pH is raised (i.e., the alkalinity of the blood is increased). This may result from the ingestion of large quantities of alkali (sodium bicarbonate) or from the loss of HCl by vomiting as in pyloric obstruction (area 1, in figure 32).

Uncompensated CO_2 deficit. In this the $[\text{H}_2\text{CO}_3]$ is reduced below normal but the $[\text{NaHCO}_3]$ is not lowered to a corresponding extent. The pH is raised. A disturbance of this nature may result from forced breathing, or the hyperventilation induced by hot baths, high altitudes or shallow breathing (p. 365). It is sometimes also referred to as "gaseous alkalosis." Partial compensation occurs as evidenced by the reduced excretion of acid and ammonia in the urine and the increase in the urinary bicarbonate (areas 2 and 3).

Compensated alkali excess. The $[\text{NaHCO}_3]$ is raised but a parallel rise occurs in $[\text{H}_2\text{CO}_3]$. The pH is there-

from the ingestion of mineral acids or acid producing salts (CaCl_2 , NH_4Cl). This and (9) are the acid-base states to which the term "acidosis" has been usually applied. The compensatory adjustments are evident in the increased acid and ammonia excretion in the urine and the lowered CO_2 tension in the alveolar air. Alkali deficit may also result from the increased excretion of base as occurs in dehydrated states (p. 17) and in animals following the production of a pancreatic fistula (area 6).

Compensated CO_2 deficit. This is a reduction in $[\text{H}_2\text{CO}_3]$ and a parallel reduction in $[\text{NaHCO}_3]$. The pH is therefore normal. This state results from less severe grades of the conditions which cause (2) above. The excretion of NaHCO_3 by the kidney is much slower than the excretion of CO_2 by the lungs, so a condition

of CO_2 deficit which is uncompensated to start with, later tends to become compensated (area 6).

Uncompensated CO_2 excess. $[\text{H}_2\text{CO}_3]$ is increased but is not balanced by a proportional rise in $[\text{NaHCO}_3]$. The pH is lowered (i.e., blood is less alkaline). This is sometimes referred to as "gaseous acidosis." Such a state results from a hindrance to the excretion of CO_2 as may occur in pneumonia, obstruction to breathing or depression of the respiratory center by morphine. There is partial compensation, i.e., the bicarbonate is raised above the normal and there is an increased excretion of acid and ammonia by the kidneys (areas 7 and 8).

Uncompensated alkali deficit. $[\text{NaHCO}_3]$ is reduced without there being a parallel reduction in $[\text{H}_2\text{CO}_3]$. The pH is lowered (i.e., the blood becomes less alkaline). Such an acid-base state occurs when large quantities of fixed acids— β -hydroxybutyric and aceto-acetic—are produced as in diabetic coma and in the terminal stages of nephritis when acid excretion is greatly impaired. The plasma bicarbonate is severely depleted; the CO_2 combining power of the plasma may be less than 20 volumes per cent (area 9).

It will be evident after a consideration of some of the foregoing acid-base states that the terms "acidosis" and "alkalosis" if used to denote respectively a fall or a rise in plasma bicarbonate are misleading, since the blood may be no more acid or alkaline than normally. For example, in (2) above, the blowing off of CO_2 will result in a certain degree of compensatory reduction of NaHCO_3 . The reduction in the alkali reserve would therefore entitle it to be called acidosis though the blood was actually more alkaline than normally. In (8) on the other hand the blood is less alkaline than normally yet a certain degree of compensatory increase in the alkali reserve would have occurred. The term alkalosis would therefore apply, though its use would give an erroneous idea of the true state of the acid-base balance. On account of the ambiguity of these terms and the confusion which is likely to arise from their use it has been recommended by the British Medical Research Council that the term *acidemia* be used for a state in which the pH is lowered and that the term *acidosis* be restricted to indicate a lowered alkali reserve with unaltered pH. The term alkalosis would be retained as the corresponding term to indicate the reverse condition, namely an increase in the reserve alkalinity. The term *alkalemia* would indicate a blood state in which the pH was raised.

MEASUREMENT OF THE HYDROGEN ION CONCENTRATION OF THE BLOOD

(1) *Electrometric method*

(a) *By means of hydrogen electrodes.* Two hydrogen electrodes are employed. The method is

derived from the fact that in a suitable concentration cell a difference of potential between a metal electrode (e.g., zinc) and a solution of its ions (e.g., zinc sulphate) is set up which is proportional to the ion concentration. A hydrogen electrode, composed of platinum black saturated with hydrogen gas is therefore used to determine the hydrogen ion concentration of a solution. One of a pair of hydrogen electrodes is placed in a solution of known hydrogen ion concentration and the other in the unknown solution. When the two electrodes are connected an electromotive force is developed from which the hydrogen ion concentration may be calculated. Another electrometric method involves the use of quinhydrone—*quinhydrone electrode*. One platinum or gold electrode is placed in a solution of known hydrogen ion concentration; and the other dips into the unknown solution. A small quantity of quinhydrone is added to each solution. The quinhydrone undergoes oxidation to quinone or reduction to hydroquinone according to the hydrogen ion concentration of the solution. A potential difference is set up between the two electrodes and from its magnitude the H ion concentration is calculated.

(b) *By means of the glass electrode.* Within the last few years this method has come into very general use for pH determinations of biological materials. Like the hydrogen electrode the potential of the glass electrode, in an electrical system similar to that just described for the latter, varies with changes in pH. It is standardized against the hydrogen electrode. The glass electrode has the great advantage that it is unaffected by oxygen, protein content and other substances in the test material which interfere with the accuracy of other methods. Theories as to its action cannot be discussed here; the reader is referred to Dole's book, "Experimental and Theoretical Electrochemistry."

(2) *Colorimetric method*

In the method of Levy, Rowntree and Marriott as modified by Dale and Evans, the blood is placed without loss of CO_2 in a collodion sac and dialyzed for 15 minutes against a solution of normal saline. A few drops of 0.02 per cent of the indicator neutral red are added to the dialysate. The latter is then placed in a comparator and its color matched with that of a phosphate mixture of known pH and containing neutral red in the same concentration as the blood dialysate. The reader is referred to Dale and Evans' article for the details of the method.

It might be thought that the H ion concentration could be reduced through the dilution of the analyzed substance by the saline in the apparatus. But, since the pH of a buffered solution depends on the *ratio* of free to bound acid and this of course will not be altered, so, moderate dilution does not effect the result. In the colorimetric method of Cullen, the pH is determined directly (i.e., without dialysis) upon plasma which is diluted 20 times; phenol red is used as indicator. In this method a correction must be made for dilution and also for protein content.

(3) From the $H_2CO_3/NaHCO_3$ ratio

The total CO_2 in a sample of plasma is obtained as described on page 107. The free CO_2 , i.e., the CO_2 in simple solution, is obtained by calculation from the partial pressure of CO_2 with which the sample was equilibrated. The calculation is made as follows. The figure for the partial pressure of CO_2 is multiplied by the absorption coefficient of CO_2 in plasma, which at $38^\circ C$. is 0.510 (p. 314). If, then, the partial pressure of CO_2 is 40 mm. Hg

(as in normal arterial blood), the quantity of gas dissolved in 100 cc. of plasma is

$$40 \times \frac{100 \times 0.510^*}{760} = 2.68$$

The total CO_2 is, say, 56 volumes per cent. Then the combined CO_2 is $56 - 2.68 = 53.32$ volumes per cent.

The pH may now be calculated from the Henderson-Hasselbalch equation (pp. 102 and 337).

$$pH = pK_1 + \log \frac{[BHCO_3]}{H_2CO_3}$$

The value of pK_1 † for plasma is 6.10, therefore

$$pH = 6.10 + \log \frac{53.32}{2.68}$$

* $100 \times \frac{0.510}{760} = 0.0672$ is a constant factor by which the CO_2 partial pressure (in mm. Hg) is multiplied to give the volumes of dissolved CO_2 .

† K_1 includes the first dissociation constant of H_2CO_3 and a figure representing the dissociation of $NaHCO_3$ under the conditions existing in plasma.

SECTION II. THE CIRCULATION OF THE BLOOD

CHAPTER XIV

THE DYNAMICS OF THE CIRCULATION

GENERAL OUTLINE OF THE VASCULAR SYSTEM

The main anatomical features of the circulatory system may be very briefly recalled. The vessels constituting the vascular bed differ widely in their calibers in different regions and on the basis of their size, structure and physiological relationships are divisible into four main groups—the *arteries*, *arterioles*, *capillaries* and *veins*. The arteries are constructed to withstand a high pressure. Their walls are thick and contain a large proportion of elastic tissue and some involuntary muscle fibers, an outer sheath of connective tissue and an inner lining of endothelial cells. The outer coat is called the *tunica adventitia*, the middle coat the *tunica media* and the inner coat the *tunica intima*. The relative proportions of muscular and elastic tissues vary with the size of the artery. The largest vessels such as the aorta and the pulmonary artery, are relatively poor in muscular tissue but contain a large proportion of elastic fibers. The medium sized arteries contain a relatively large amount of muscle and less elastic tissue, while in the smaller vessels the muscle is greatly in excess. The walls of the arteries are supplied with minute vessels—*vasa vasorum*—which ramify in the outer and middle coats. They also are furnished with nerves. As the arterial system is traced peripherally the vessels are found to break up into innumerable branches whose calibers become reduced with successive divisions. Finally minute vessels—the *arterioles* are formed. These vary in size but on the average are about 0.2 mm. in their outside diameters. Their walls are relatively thick and composed almost entirely of smooth muscle lined by an endothelial layer and sheathed by a scanty adventitia. The muscle fibers are supplied with excitor and inhibitor nerves (p. 232). The arterioles after a course of variable length lose their muscular and connective tissue coats while the inner endothelial tubes that remain are continued on as extremely fine, hair-like vessels, the *capillaries*. The capillaries, a number of which arise from a single arteriole, are from 8 to 12 microns in diameter and about a millimeter long. Lying upon the outer surface of the capillary wall in amphibians and certain other cold-blooded vertebrates a scattering of peculiar cells with a number of long processes is to be seen. These are called after their discoverer, Rouget cells (see also p. 265). The processes of the neighboring Rouget cells join with one another to form a loose mesh-work which encloses the capillary. The capillaries form maze-like plexuses with one another and connect the arterial and venous systems. Their venous ends converge to form first the smaller *veins* or

venules. By the confluence of these to form larger channels, and the successive junctions of veins of ever increasing caliber, the blood is finally poured into the right auricle by two large trunks, the superior and inferior *venae cavae*.

The veins have much thinner walls than the arteries, but like these they possess three coats—intima, media and adventitia. The middle coat is only a fraction of the thickness of that of a corresponding artery. It is composed of a relatively small amount of unstriped muscle and a large amount of connective tissue: the elastic tissue is scanty. The outer coat of the vessel is disproportionately thick, being several times thicker than the tunica media. The valves which are present in some of the larger veins are formed by foldings of the tunica intima.

The course of the blood through the body from the left ventricle to the right auricle is spoken of as the *greater* or *systemic circulation*. From the right auricle the blood enters the right ventricle from which it is discharged into the pulmonary artery and thence through the *lesser* or *pulmonary circulation*. The heart serves as a two cylinder pump situated between these two systems. The left ventricle receives arterial blood from the lesser circulation, and drives it through the systemic vessels. The right ventricle is supplied with venous blood from the systemic vessels and pumps it through the pulmonary circuit. Both sides of the heart contract synchronously and obviously must eject the same quantity of blood in a given time. Otherwise blood would be dammed back in some part of the circulation.

THE PRINCIPLES GOVERNING THE FLOW OF A LIQUID THROUGH A SYSTEM OF TUBES

The vascular system may with advantage be considered here in its purely physical aspect, and its more physiological characters be left to be dealt with later. The movement of the blood within the vascular channels is governed by those physical laws which govern the flow of liquids in any other closed system of cylindrical tubes. For this reason the dynamics of the circulation may be more simply explained and the more readily appreciated from illustrations furnished by artificial models.

Figure 33 represents a model comprising a reservoir and a long horizontal tube from which upright tubes of the same bore and numbered 1 to 6 lead off. The

horizontal tube can be closed or opened to any desired extent by means of the stop-cock T. The level of fluid in the reservoir is at all times kept constant by means of the faucet.

If the stop-cock be closed and water poured into the system, the fluid will rise to exactly the same heights in the reservoir and all the side tubes. The heights of the liquid in the reservoir and in the upright tubes represent a certain amount of *potential energy*—energy of position. If the fluid were allowed to flow, a certain proportion of the potential energy would be converted into *kinetic energy*—energy of motion. The total height of the column of fluid in the reservoir is spoken of as the *reservoir head*, H . The height to which the column has risen in a given side tube represents the pressure that is exerted at that point upon the wall of the horizontal tube—that is, the lateral pressure. Thus if the column, say, is 100 mm. high then the lateral pressure in the horizontal tube at that point is obviously 100 mm. of water. In this model the heights of the narrow columns are the same as the reservoir head, therefore the lateral pressure and the total potential energy are of equal value, in other words, the entire potential energy available is exhibited as pressure.

Let us now suppose that the stop-cock is opened to its fullest extent or removed entirely as in figure 34. Let it also be assumed that the outflow of liquid is at a hypothetical maximum—just as though a large opening were made in the bottom of the reservoir chamber—and that there is no friction or other impediment to the outflow. In such an instance the entire potential energy would be transformed into energy of flow (kinetic energy). The fluid would not rise at all in the side tubes; that is, there would be no lateral pressure. The fluid would leave the system at a velocity equal to that which the same body of water would attain if it fell free through a vertical distance equal to its own height, i.e., the height of the reservoir column. From the two foregoing examples it is seen that a given amount of potential energy may remain as such, or, theoretically, be converted entirely into kinetic energy.

In figure 35 the stop-cock is opened. Part of the total potential energy is now utilized in giving velocity to the flow of fluid in the horizontal tube. The remainder is exhibited as lateral pressure which can be expressed as the height in centimeters of the fluid in the side tubes. The velocity of flow (kinetic energy) will increase or diminish and the lateral pressure fall or rise reciprocally. From these considerations it may be stated that: *the greater the velocity of outflow from the system the lower will be the lateral pressure and vice versa.*

When, as in figure 35, the stop-cock is partially open and, as in practice, the flow along the horizontal tube is impeded by friction, the water rises only part way in the side tubes, and not to the same height in each. The level of the column in the first tube is a little lower than that of the fluid in the reservoir which is kept constant by the supply faucet. The second column is

lower than the first, the third than the second and so on, there being a steady decline in the levels of successive tubes. A line joining the menisci is straight, and falls a little below the surface of the fluid in the reservoir.

The difference between the level of the first column and that of the reservoir is evidently due to the flow of liquid along the horizontal tube, since when, as shown in figure 33, there was no flow the two levels were the same. This difference between the height of the reservoir and that of the first column represents the

FIG. 33. Description in text.

FIG. 34. Description in text.

FIG. 35. Description in text.

proportion of potential energy which has been converted to kinetic energy, i.e., which is responsible for the velocity of flow along the horizontal tube. It is therefore termed the *velocity head*, V . That the drop in lateral pressure in tube 1 is actually due to the velocity of the flow may be shown by having its lower end project into the horizontal tube and bent so that its opening faces the stream as in figure 36. When this is done the velocity of the fluid causes the level of column 1 to attain practically the same height as the level of the reservoir column. If the opening is turned in the opposite direction as in tube 3, then the level of the column is depressed an equal distance below its original level as a result of the velocity in the horizontal tube.

The difference in the water levels of successive tubes cannot, however, be explained by a progressively greater amount of potential energy being converted into kinetic energy, the velocity of flow must be the same

throughout the length of the horizontal tube since its bore is uniform and in a given time the same amount of fluid that enters at one end from the reservoir must leave by the other. Furthermore, if a tube (6), say, be extended and turned to face the stream (fig. 36) the fluid in it rises, but the rise in this tube only partially annuls the original fall in its level and is precisely equal to the rise which occurred under the same circumstances in tube 1, i.e., it is equal to the velocity head.

The progressive fall in lateral pressure along the system is due to the energy lost in overcoming friction. At the outlet the lateral pressure has fallen to zero. Evidently then at this point the whole of the potential energy not used in giving velocity to the fluid has been consumed in overcoming frictional resistance. So, R. (fig. 35) will represent this lost energy and is called the *resistance head*. The proportion of energy used in this way is very small in tube 1 since the length of horizontal tube traversed by the fluid is very short, but increases at the expense of the lateral pressure, in proportion to the distance along the horizontal tube

FIG. 36. Description in text

traversed by the fluid and the greater frictional resistance that must therefore be overcome.

If the velocity be increased by further opening the stop-cock and allowing more fluid to flow out two effects will be caused.

(a) The lateral pressures in all the tubes will show a greater fall below the level of the reservoir column since more potential energy will be converted into kinetic energy; the velocity head is increased.

(b) The slope of a line joining the menisci of the fluid columns will be steeper, i.e., the differences in pressure between successive tube levels—the *pressure gradient*—will be greater; more energy will be used in overcoming friction for the resistance due to friction increases approximately in proportion to the square of the velocity. (See 3 below.) Reducing the outflow from the tap will produce the reverse effects.

On the other hand, if the diameter of the outlet from the horizontal tube remain the same but the height of the fluid in the reservoir be raised or lowered, thus increasing or decreasing the pressure gradient, then the velocity will vary proportionately.

Some of the more important laws governing the flow of liquids through rigid tubes of small caliber may now be briefly summarized.

- (1) *Lateral pressure is inversely proportional to the velocity.*
- (2) *Resistance varies with the length of the tube, i.e., is proportional to the frictional surface.*
- (3) *Resistance is proportional, approximately, to the square of the velocity; with a constant velocity the resistance is inversely proportional to the cross area of the tube.*
- (4) *The sectional area of the tube remaining constant, then the velocity of flow of a given fluid is proportional to the pressure gradient.*

FIG. 37. Description in text.

- (5) *The pressure head remaining constant, then the velocity is directly proportional to the sectional area of the tube, but the quantity of fluid passing through the tube per unit of time—volume flow—is proportional to the fourth power of the diameter of the tube. (Poiseuille law.)*

So far, a model has been dealt with in which the horizontal tube is of uniform caliber throughout. But if the diameter of the tube at any part be increased the velocity of flow through this part will diminish; conversely the velocity will increase through a narrowed section of the tube. We must therefore state a sixth law.

- (6) *In a tube of varying diameter the velocity is inversely proportional to the sectional area.*

In figure 37a, the horizontal tube is shown with a dilated region near its center. Below the model is a more diagrammatic representation (b). The arrows indicate the flow of water through the tube. Obviously since liquids are practically incompressible, the same quantity of water must, in a given time, leave the tube as enters it. Consequently, equal quantities of water

must take the same time to pass any point along the tube. Section 2 of the tube has precisely the same capacity as section 1 or 3. But the length of section 2 is only half that of either of the other sections. It is clear then that the body of water in section 2 has only half the distance to travel as has an equal body in either section 1 or 3. The velocity of the water particles must therefore be reduced by half.

Since the lateral pressure is inversely proportional to the velocity, then the level of the fluid column in tube 4 leading from the dilated section will be higher than the levels of the tubes on either side. These facts explain why an abnormal dilatation in the vascular system, such as an aneurysm or a varicose state of the veins tends to increase. A vicious circle is established and the sacculation tends "to go from bad to worse," since the widened bed of the stream causes a local reduction in velocity and a consequent increase in

FIG. 38. Description in text.

pressure. This in turn causes a stretching of the vascular walls and further dilatation, and so on.

It is immaterial whether the increase in the cross area of the stream is brought about by a single dilatation or is accompanied by a division of the tube into a number of smaller channels as obtains in the vascular system (cf. fig. 37 c and fig. 41, p. 118). So long as the sum of the sectional areas of all the subdivisions is increased, no matter how small these are individually, a reduction in velocity results.

The horizontal tube of the model in figure 37a is narrowed between the upright tubes 1 and 3. The velocity in this section is therefore increased and the pressure reduced as is shown by the height of the fluid in the second side tube.

In the final model, figure 38, the tap has been placed half way along the horizontal tube so as to divide the system into two sections. If the tap be partially closed, a sharp drop in the curve of lateral pressures will occur between the tubes on the left of the tap, and those on the right. That is, the model has been divided into a high and a low pressure system. Increasing the flow through the tap will, as we know, cause the pressure in the left hand section to fall and the pressure in the right hand section to rise. Reducing the flow through the tap, on the other hand, causes contrary effects in the two systems.

THE APPLICATION OF SOME OF THE FOREGOING PRINCIPLES TO THE CIRCULATION OF THE BLOOD

The heart, of course, is the source of the energy whereby the blood is driven through the system at a given pressure and velocity.

THE ENERGY OF THE VENTRICULAR CONTRACTION— THE WORK OF THE HEART

The energy derived from the contraction of the cardiac muscle is expended mainly in overcoming the frictional resistance which opposes the flow of blood through the systemic vessels from the left to the right side of the heart in the case of the left ventricle, and through the pulmonary circuit in the case of the right. The energy expended in this way and dissipated as heat amounts to from 80 to 95 per cent of the total calculated energy (see below). The remaining fraction of the total energy liberated by the cardiac muscle appears as mechanical or external work. The latter was found by Evans and Matsuoka, employing the heart-lung preparation (p. 214), to amount to 5 or 6 per cent of the total energy when the heart was beating quietly and its output small. This figure, which represents the efficiency of the cardiac machine, is therefore very low under these conditions. The efficiency rises, however, to 20 per cent or higher when, as in muscular exercise, the output of blood from the heart per minute is maximal and the cardiac action is vigorous. That is to say, the efficiency of the cardiac muscle rises up to an optimum load as its work increases. Also for a given load it works more efficiently at slow than at rapid rates.

The total energy expenditure of the cardiac muscle can be calculated from the oxygen consumption of a heart-lung preparation (p. 214). Now, in the consumption of 1 liter of oxygen the heat which is generated amounts to about 5 large calories. The work equivalent of one calorie is 426.5 kilogram-meters (or 3086 foot-pounds). The consumption of 1 liter of oxygen, therefore represents a total energy expenditure of $426.5 \times 5 = 2132.5$ kilogram-meters. The proportion of the total energy expenditure appearing as work gives the efficiency of the cardiac machine. The actual work performed is calculated from the following formula—

$$W = \frac{7}{6} QR + \frac{mV^2}{g}$$

Where W = total work in kilogram-meters per hour, Q = volume of blood expelled in liters per hour, R = mean arterial blood pressure in *meters* of blood. This latter is obtained by multiplying the figure for the

arterial blood pressure in millimeters of mercury by .0135; mercury is about 13.5 times heavier than blood. The pressure in the right ventricle is only one-sixth of that developed in the left so to obtain the value of QR for the whole heart this factor is multiplied by $\frac{1}{6}$.

The factor QR means, in brief, that a certain amount of blood Q is expelled from the heart against a resistance R and that the work done is equivalent to that which would be required to raise the weight of blood through a certain height. This latter corresponds in a given instance as mentioned above to the arterial blood pressure (p. 120). When the output of the heart is small this part of the equation represents by far the greater part of the work performed. When the body is at rest, 99 per cent of the work performed by the heart (which as mentioned above is from 5 to 6 per cent of its total energy expenditure) is employed in raising and maintaining the pressure of blood in the arterial system and in expanding the elastic arterial walls.

The factor $\frac{mV^2}{g}$ represents that portion of the work performed by the heart in giving velocity to the blood. That is, it gives the amount of total energy that is converted into kinetic energy. When the cardiac output is small this factor as just indicated is negligible, amounting to less than 1 per cent of the total work performed.

In the above expression m = weight of blood in kilograms per hour, V = mean velocity of the blood in meters per second at the root of the aorta, g = acceleration due to gravity, a constant amounting to 9.80 meters per second, per second.

It has been pointed out by Evans that since in calculating the kinetic energy of the cardiac contraction it is the mean velocity of the blood as it is expelled from the ventricle, i.e., during the ejection period of the cardiac cycle, that is required rather than the mean velocity of the blood in the aorta throughout the entire cycle, a correction must be employed to obtain the true value. The velocity of the blood issuing from the ventricle rises to a maximum about the middle of, and falls to zero at the end of the ejection period. The velocity varies inversely with the length of this period. Therefore, when the latter has the usual duration of about $\frac{1}{3}$ of the cardiac cycle the value for the velocity of the blood in the aorta must be multiplied by the square of $\frac{3}{2}$ or by 7, approximately. The equation therefore becomes $\frac{7mV^2}{g}$, or the more generally applicable one, $\frac{m \cdot VC^2}{gE^2}$, in which C = duration of cardiac cycle and E = duration of ejection period.

The kinetic factor has the same value for each ventricle, since identical quantities of blood are ejected at equal velocities from each side of the heart at each beat. When the output of the heart is large the kinetic factor can be no longer neglected in calculating the work of the heart. It reaches an importance com-

parable with the pressure factor, QR. The magnitude of these two factors may be compared by the following numerical examples under conditions of small and large systolic outputs respectively.

A. Heart of dog, small output, 6 liters per hour.

Mean arterial blood pressure 100 mm. Hg. Mean velocity of blood at the root of the aorta, 0.085 meters per second.

$$\begin{aligned} W &= \frac{7}{6} QR + \frac{7mV^2}{g} \\ &= \frac{7(6 \times 100 \times 0.013)}{6} + \frac{7 \times 6(0.085)^2}{9.8} \\ &= 9.10 + 0.031 \\ &= 9.131 \text{ kilogram-meters per hour} \end{aligned}$$

B. Forcibly beating heart, with output of 90 liters per hour.

Mean arterial blood pressure 100 mm. Hg. Mean velocity in aorta 1.27 meters per second.

$$\begin{aligned} W &= \frac{7}{6} QR + \frac{7mV^2}{g} \\ &= \frac{7(90 \times 100 \times 0.013)}{6} + \frac{7 \times 90 \times (1.27)^2}{9.8} \\ &= 136.5 + 103.7 \\ &= 240.2 \text{ kilogram-meters per hour} \end{aligned}$$

The kinetic factor in the above example is seen to constitute a large part of the total work performed. If output is still further increased, say to 120 liters per hour, then the value of this factor may exceed the pressure factor QR; it may constitute 60 per cent of the total work. The disproportionate increase of kinetic factor over the QR factor is due to the fact that the latter increases in direct proportion to the output, whereas the former increases as the cube of output. For instance, when as in the above example the output is increased from 6 to 90 liters per hour, that is 15 times, the QR factor is increased to the extent $(9.10 \times 15 = 136.5)$. The value of the kinetic factor, however, is increased over 3000 times since mass of blood is increased 15 times, and V^2 is increased $15 \times 15 = 225$ times, and $\frac{7m(V)^2}{g}$ is increased $15 \times 15 \times 15 = 3375$ times. Thus the value of the kinetic factor in example A is 0.031, in example B an output 15 times greater it is approximately $0.031 \times 15^3 = 103.7$. If the output is increased from a very small magnitude, say of two or three liters per hour, to one very much greater, 120 liters per hour, the value of the kinetic factor in the latter instance will be increased 6000 times or more.

By employing data obtained through indirect measurements of the cardiac output (p. 228) and the blood pressure (p. 125) it is possible to arrive

ation of the work performed by the human heart. The average quantity of blood discharged from the ventricle (Q) when the body is at rest is around 5 liters per second. If the mean blood pressure is 93 mm. Hg then the value of R is 1.35 meters.

Therefore, $\frac{7}{6} \times \frac{60}{1000} \times 1.35 = 0.93$ kilogram-meters per second, or over 5 kilogram-meters per minute, is the work performed by the average heart during rest. With this small cardiac output, the kinetic factor may be neglected. Evans took the diameters of the aortic and pulmonary orifices to be 2.5 cm., the duration of systolic discharge as 0.3 second and the ventricular output as 60 grams per beat, obtaining a figure of 1.35 meters per second as the velocity of discharge during rest.

Then, on the other hand, the output is of large magnitude (over 25 liters per minute) as in strenuous exercise the velocity of the blood as it leaves the ventricle is over 2 meters per second. The kinetic factor calculated from the output and velocity of ejection amounts to over 10 per cent of the total work performed. The latter may reach a value exceeding 10 kilogram-meters—sufficient to lift the weight of an average-sized man some three and a half feet per minute.

In aortic stenosis, with marked narrowing of the aortic ring, the velocity of ejection is greatly increased above the normal even during rest. The work of the ventricle may be nearly doubled, and the increase is due to the enormous increase in the kinetic factor. It may, even in the absence of muscular exertion, almost equal the pressure (QR) factor. That is, the kinetic factor will then increase the work of the heart nearly 100 per cent.

In hypertension (p. 128), R , and consequently the work of the heart, is of course increased.

THE PRESSURES AND VELOCITIES OF THE BLOOD IN DIFFERENT PARTS OF THE VASCULAR SYSTEM

The arteries constitute a high pressure system which is separated from the venous or low pressure system by the *arterioles*. These latter represent the stopcocks in the artificial models (pp. 113–115). The sphincter-like arrangement of the smooth muscle in the walls of these vessels enables their calibers to be increased or diminished; when more blood issues from the arterial system into the capillaries and veins, the pressure in the arteries falls whereas it in the capillaries and veins tends to rise. If the arteriolar calibers diminish, capillary and venous pressure changes of a reverse order result. The pressure throughout the arterial system falls in a gradual slope from the larger to the smaller branches as a result of the greater distance through which the blood has travelled before reaching the latter vessels and, as a consequence, of a pro-

portion of the energy derived from the cardiac contraction having been consumed in overcoming frictional resistance. The pressure fall from the aorta to the small arteries amounts to about 20 mm. of mercury. The greatest fall in pressure occurs beyond these vessels, namely during the passage of the blood through the arterioles. The pressure drop in this part of the circulation amounts to from 50 to 60 mm. Hg. (fig. 39 and fig. 42, p. 121).

Let us now consider the causes of this abrupt fall. We find that when the blood reaches the region of the arterioles the frictional surface is

FIG. 39. Diagram showing the pressure and velocity of the blood in different parts of the vascular system (modified from Fredericq). Note the relation between blood velocity and vascular area, and the absence of rhythmical variations in pressure and velocity in the capillaries and veins [see also p. 122].

greatly increased as a result of the breaking up of the vascular bed into smaller channels. Yet the total cross area of the blood stream at this point is not greatly enlarged. As a matter of fact it is increased comparatively little. The distinction may be rendered clearer if reference be made to the diagram (fig. 40). The large circle A represents the circumference of the aorta. The column of blood within has a certain sectional area and a certain surface with which it and the arterial wall are in contact. Frictional resistance is proportional to the extent of this surface. In B, which represents the arteriolar region, a somewhat larger sectional area is composed of the sectional areas of a very large number of separate blood columns.

The sum of all these cylindrical surfaces must be enormously greater than that of the single aortic blood column. Since the total sectional area of

FIG. 40. Description in text.

third layer glides upon the second, the fourth upon the third, and so on. Thus the cross-section of a moving stream consists of a series of concentric layers like the skins of an onion. For this reason simple roughening of the interior of an artery causes little increase in the resistance to the flow of blood. The movement of one layer upon the next diminishes progressively in a central direction so that in the axial portion of the stream the liquid is free from friction and its velocity is maximal. This more rapid movement in the axis of the stream can be observed in blood flowing in the small vessels of a transparent tissue. The corpuscles near the vessel wall progress comparatively slowly while those in the axial stream are swiftly moving. The greater the viscosity which the liquid possesses, the further centrally do the frictional layers extend and the smaller in extent

FIG 41. Diagrammatic representation of the expansion of the vascular bed in the capillary area ("capillary lake").

the vascular bed in this situation is only moderately increased, the blood velocity shows only a moderate reduction (p. 114). And, since the frictional resistance is proportional to the square of the velocity, the effect of the increased surface upon the resistance to the flow of blood through the arterioles will be very great.

In the case of liquids flowing in narrow tubes friction is not developed between the moving liquid column and the inner surface of the tube, but between the molecules of the liquid itself. The outer layer of flowing liquid in contact with the lining of a tube is stationary. No friction therefore develops between this layer and the walls of the tube. The tubular layer of liquid next within this stationary layer rides or "slips" upon it, the

is the frictionless "core." For a given liquid the absolute depth of the layers is practically the same whether the diameter of the liquid column is great or small. Consequently in the aorta where the cross area is great the proportion of this wherein friction is developed is quite small as compared with that of the slender blood columns in the arterioles where the greater part of the stream may be occupied by frictional layers.

Beyond the arterioles through the capillaries and veins to the right side of the heart, the slope of pressure is again a gradual one. A further quota of energy is expended in propelling the blood along these vessels against resistance. The latter, though of very moderate degree, is such that by the time the blood has reached the right auricle

the pressure has been reduced to almost zero—about 5 mm. of water (see also p. 137).

The *variations in velocity* throughout the vascular system are quite different from those of pressure (fig. 39). The velocity is high in the arteries (p. 146) but is reduced several hundred times in the capillaries and small veins. In the *capillary area*, though each vessel is extremely narrow, having, on the average, a diameter no greater than that of a red corpuscle, the sum of the sectional areas of these fine divisions of the vascular system is from 600 to 800 times greater than the cross area of the aorta. This broadening of the vascular bed into the "capillary lake" as this area is sometimes called, causes a proportionate slowing of the blood stream (fig. 41). The reduced velocity here has obvious advantages since it is in this region that the interchange of gases and food materials, and of waste products takes place between the plasma and the extravascular fluids. Since the velocity of the blood flow is so greatly reduced the frictional resistance in the capillary region is relatively small despite the narrowness of the individual channels. In consequence any further fall in the pressure of the blood in its passage through the capillary is of moderate degree. It amounts

under ordinary circumstances to only 20 mm. of mercury or less. The slowing of the stream would also have a tendency to raise the pressure in this region (p. 000) and so to counteract, in part at least, for the fall that would result from the increased frictional resistance. After traversing the capillary area the velocity of the blood increases again for, with the confluence of the smaller veins to form vessels of ever increasing size but fewer in number, the total cross area of the vascular bed becomes progressively reduced. The sectional area of the great veins at their point of entrance into the right auricle is only about double that of the aorta. The slowing of the current in the capillaries and its quickening in the veins, though influenced from time to time by other more purely physiological factors to be considered later, are due in the main simply to the differences in the areas of the vascular beds in the two situations. Obviously this must be so since the vascular system is closed and, except as a temporary event when the capacity of a part of the system is suddenly increased or reduced, the same quantity of blood which leaves the left ventricle must, in a given period of time, be emptied into the right auricle.

CHAPTER XV

THE ARTERIAL BLOOD PRESSURE

THE EXPERIMENTAL MEASUREMENT OF THE BLOOD PRESSURE

The pressure in the crural (femoral) artery of the horse is sufficient to raise the blood to a height of between 8 and 9 feet. That is to say, the pressure exerted upon the walls of the artery is equivalent to the pressure exerted by a column of blood of this height. This comparatively great pressure was first demonstrated by the cleric-scientist, the Rev. Stephen Hales of Teddington, England, over two hundred years ago (1733). A long glass tube was connected by means of a goose's trachea (which on account of its flexibility served in lieu of rubber tubing) to a brass cannula inserted into the animal's artery. When the blood was permitted to flow from the artery into the vertical tube it rose rapidly, but with fluctuating progress, until it reached a height of 8'3", and then oscillated above and below this level with each beat of the heart.

In man the normal pressure is considerably less than this, amounting to no more than 5 or 6 feet of blood, but in cases of hypertension (p. 128) the pressure may be sufficient to raise a column of blood to a height of 13 feet. The pressure varies within fairly narrow limits in different warm-blooded species, and there is little or no relationship between the size of an animal and the height of its blood pressure. The pressure in the rat's arteries is actually somewhat higher than that in human vessels and the arterial pressure of a mouse¹ is probably little different from that of an elephant. The blood pressure is, in general, higher in birds than in mammals whereas that of cold-blooded animals is only about one-third. Obviously the method of measuring blood pressure employed by Hales in his pioneer work has great disadvantages, both on account of the technical inconvenience, and the inaccuracy consequent upon the increase in the capacity of the circulatory system which the employment of a long section of tubing involves. For this reason the registered pressure would be considerably less than that actually existing. In order to overcome these faults the blood is not permitted to leave the blood vessel, but is made to exert its pressure upon mercury placed in a U-shaped tube. Since mercury is thirteen and a half times heavier than blood a column of the metal is raised a corresponding fraction of the distance (about 5 inches) that the blood itself would rise. The mercury being confined within a

tube doubled into the form of a U this distance is further reduced by half. The height of the pressure is indicated by the difference in levels of the two limbs of the U. Ever since Poiseuille in 1828 introduced this instrument—the *mercury manometer*—it has been customary to express the pressure of the blood in millimeters of mercury. In order to prevent coagulation of the blood, which was another serious objection to Hales' original method, the tubing connecting the cannula in the artery with the manometer is filled with a solution of sodium citrate, or other anticoagulant fluid. Ludwig improved the method by making it self-recording. He placed a float upon the mercury column, to the float was fastened a long stiff wire bearing a writing point. By having the latter inscribe its movements upon a moving surface—a revolving drum covered with smoked paper (*kymograph*)—permanent tracings of the blood pressure were obtained.

THE SYSTOLIC, DIASTOLIC, MEAN AND PULSE PRESSURES

Hales in describing his experiment speaks of the blood column, after it had ceased to rise further in the tube, oscillating above and below a mean level. To quote his own words, "When it (the blood) was at its full height it would rise and fall at, and after each pulse, 2, 3 or 4 inches." In blood pressure tracings taken by Ludwig's method these same fluctuations in pressure are seen as small waves synchronous with the heart beats (fig. 42). The crests of the waves which represent the maximal pressure correspond to the contraction or systole of the ventricle. The maximal pressure is consequently known as the *systolic pressure*. The troughs of the waves, i.e., the points of minimal pressure coincide with the end of the resting phase or diastole of the cardiac cycle (p. 168). This level is called the *diastolic pressure*. The *mean pressure* is usually given as half the sum of the values for the systolic and diastolic pressures.²

¹ This is not strictly accurate and a true numerical expression in millimeters of mercury of the mean pressure is not simply the average of the values of the systolic and diastolic pressures, i.e., the sum of these values divided by 2 (arithmetic mean). The average pressure throughout the cardiac cycle, i.e., the true geometric mean, is somewhat lower than this, lying nearer the diastolic than the systolic pressure. If the pressure fell in a steady slope from its systolic to its diastolic level throughout the cardiac cycle, and the pulse wave (see fig. 54) inscribed a perfect triangle, the arithmetic and geometric means would be identical. The descending limb of the pulse curve, however,

² The carotid blood pressure (systolic) of the dog is from 120 to 165 mm. Hg, and of the horse from 135 to 150 mm. Hg. The following values for the blood pressures (average systolic in mm. Hg) were obtained by Woodbury and Hamilton for a number of different species; mouse, 113; rat, 187; canary, 220; robin, 118; frog, 43; turtle, 44; and carp, 43. These pressures were determined by means of a hollow needle inserted through the chest wall into the left ventricle.

The difference between the diastolic and systolic pressures is the *pulse pressure*. This, clearly, is caused by the ejection of blood into the aorta during systole. Its magnitude, other things being equal, will vary with the quantity of blood ejected by the heart at each beat.

The diastolic pressure represents the constant load which the arterial walls are called upon to bear and the resistance which the ventricular contraction must overcome to throw open the aortic valves. It shows a steady but slight decline from the larger to the medium sized vessels. The systolic pressure shows a fall between the larger and the smaller arteries which though not great is much more pronounced than that which occurs in the diastolic. On this account the two pressures tend to become more nearly equal toward the periphery, the pulse pressure being reduced. Since the pulse pressure is the difference between

FIG. 42. Showing the phases of the arterial blood pressure.

the systolic and diastolic pressures, it may be reduced by an alteration in one or other of these. A rise in the systolic or a fall in the diastolic will cause the pulse pressure to increase; while a fall in the systolic or a rise in the diastolic, will lower the pulse pressure. If both systolic and diastolic pressures rise or fall to an equal extent the pulse pressure remains unchanged. The mean pressure will rise as a result of a rise in either the diastolic or systolic pressure or of both together and will fall when a reduction of either or of both of these pressures occurs.

THE SEVERAL FACTORS WHICH COMBINE TO MAINTAIN THE NORMAL ARTERIAL PRESSURE

These factors are five in number and though certain points concerning the rôle which some of

presents one or more secondary waves which prevent it from assuming the purely triangular form.

them play in the maintenance of the blood pressure have been touched upon more or less incidentally in previous sections, it will be necessary to consider them here more categorically. They are—

- (1) *The pumping action of the heart*
- (2) *The peripheral resistance*
- (3) *The quantity of blood in the arterial system*
- (4) *The viscosity of the blood*
- (5) *The elasticity of the arterial walls*

(1) *The pumping action of the heart.* The means by which the cardiac contraction exerts its effect upon the arterial blood pressure is, obviously, through the quantity of blood which it is capable of discharging into the aorta in a unit period of time, i.e., upon the output of the heart per minute (minute volume, p. 224). When more blood is forced into the already filled arterial system, it cannot escape at once from the system in the same amount as it is thrown into the aorta, so the arterial walls become stretched. The pressure rises until the velocity of flow through the arterioles is great enough to balance again the outflow from the system with the inflow. Hales grasped this fundamental fact when he wrote, "the real force (pressure) of the blood in the arteries depends on the proportion which the quantity of blood thrown out of the left ventricle in a given time bears to the quantity which can pass through the capillary arteries (arterioles) into the veins at that time."

(2) *The peripheral resistance.* This resides in the arterioles (see also p. 117) and to a less extent in the capillaries. By far the greater part of the peripheral resistance of the circulatory system is constituted by the arterioles of the abdominal viscera—the so-called splanchnic area. Stimulation of the great splanchnic nerve (p. 940) which innervates the rings of muscle fibres in the walls of these vessels causes their constriction, and consequently a reduction in the outflow from the arterial system. As outlined in the last section the pressure will continue to rise until inflow and outflow are again balanced. In the absence of compensatory changes in the other factors concerned in the maintenance of the pressure this remains at the higher level so long as the constriction persists. Dilatation of the vessels, i.e., reduction in peripheral resistance, will of course be followed by the opposite effect. When the vessels of the splanchnic area are fully dilated they are capable of accommodating almost all the blood in the body; in such an event the blood pressure would fall to zero. The peripheral resistance might be compared to a dam in a river. If the dam is raised or lowered the water continues to rise or fall

respectively (and its pressure in consequence increases or diminishes) until it reaches the new level. From then on the quantity of water which overflows in a given time is the same as it was at the original level.

(3) *The quantity of blood in the arterial system.* In any closed system of rigid tubes fluid must fill it to capacity in order that a pressure can be developed within it. The arterial walls are distensible and elastic, and a certain degree of stretching of these must occur before any considerable pressure is created. The arterial system must be actually over-filled and the greater the extent of the over-filling the greater will be the blood pressure. Loss of blood, either of all its elements, as in hemorrhage, or of the fluid portion alone, if not compensated for sufficiently by readjustment of the other factors concerned in blood pressure maintenance, must inevitably result in a fall of pressure. Increasing the total amount of circulating fluid artificially as by the transfusion of blood or blood substitute will elevate the pressure again. Saline solution, however, as explained elsewhere (p. 39) causes a very evanescent rise, since it soon leaks from the vessels into the surrounding tissues. In animals the blood pressure may be lowered by hemorrhage to half its normal value and restored again to its original level by re-introducing into the circulation the blood which has been removed or by the infusion of an effective blood substitute (see Effects of hemorrhage, p. 21).

(4) *The viscosity of the blood.* The greater the viscosity or "thickness" of any liquid the greater is the pressure required to force it along a length of narrow tube in a given time; or if the pressure be constant the longer is the time required for it to traverse the tube. The frictional resistance which is developed between the parts of the liquid itself, that is, the internal friction (p. 118) is greater when the viscosity is high than when it is low. Viscosity depends upon the degree to which the molecules or particles of a fluid cohere. Blood is some 5 times more viscous than water.¹ With regard to the influence of viscosity upon the blood pressure, it is again a matter of outflow through the arterioles. If the driving force remains constant and the caliber of the vessels is unchanged, then the greater the viscosity the greater will be the frictional resistance developed

in this region and the less will be the quantity of fluid that will pass through in a unit of time.

The blood owes its viscosity to its colloids (plasma proteins) and to an even greater extent its suspended corpuscles; friction is developed between the surfaces of the latter and the surrounding fluid. Changes in concentration of the blood as a result of changes in protein content or in the number of its corpuscles therefore alter its viscosity; venesection by removing a quantity of blood and causing dilution of the remainder (p. 16) causes a fall in viscosity which may materially relieve the work of the heart. For these reasons viscosity is low in anemia and high in polycythemia, leukemia and anhydremia. Also changes in its chemical composition or in its gas content may alter its viscosity of the blood. Carbon dioxide increases viscosity oxygen lowers it: venous blood is, in consequence, more viscous than arterial, and high blood viscosity is usual in congestive heart failure with cyanosis. Chloroform anesthesia and narcosis with morphine are said to increase the blood viscosity. It is also raised in hyperglycemia, hypercalcemia and in acidosis.

The viscosity of most liquids is reduced by a rise of temperature—hot syrup flows more freely than cold. In muscular exercise and in fever the blood temperature is raised, the viscosity of the blood is lowered and the work which the heart is called upon to do in overcoming the frictional resistance in the smaller vessels is then appreciably reduced. Blood concentration, however, which occurs to some extent under these circumstances tends to offset the effect of temperature.

(5) *The elasticity of the vessel walls.* This is concerned mainly with the origin and maintenance of the diastolic pressure and with sustaining the mean pressure at a higher level than would be possible in a rigid system under otherwise identical conditions.

The elasticity of arterial tissue does not come into play to any notable extent with a pressure below from 30 to 40 mm. of mercury (fig. 4). Below this level there would be little stretching of the walls of the arteries which would then behave like a system of rigid tubes. At the usual diastolic pressure that exists, however, the walls are stretched and by virtue of their elasticity tend to recoil against the distending force. We have seen that the flow of blood is pulsatile in the arteries. Beyond the arterioles, i.e., in the capillaries and veins the flow is continuous. The conversion of the pulsatile flow to an even one depends upon the existence of a diastolic pressure. The physiological principles involved in the maintenance of the diastolic pressure and the disappearance of the

¹ This is an average figure. Values obtained by different observers for the viscosity of blood, taking distilled water as unity, vary considerably but the majority range between 4.5 and 5.5.

beyond the arterioles may be best illustrated by a simple artificial model similar in principle to that devised by Borelli for the same purpose some 150 years ago.

Figure 44 is represented a bulb syringe, labeled at A, and having a short tube, B, which leads into a basin of water. Leading from the opposite pole of the bulb is a longer tube, C. If the bulb be alternately compressed and released the fluid will be drawn from the basin and discharged at the mouth of the tube. If the walls of the tube be composed of some rigid material, (fig. 44, 1), it will be found that when the pump is worked the fluid issues from the tube in spurts or jets synchronous with each stroke, but no flow occurs between the strokes. An increase in the frequency or force of the strokes does not alter

FIG. 43. Curves of distensibility of a vein (upper curve) and of an artery (lower curve). The figures at the left side of the diagram represent the capacity of the vessel when distended under a certain pressure, expressed by the figures on the base line in mm. Hg. (after Starling, constructed from figures given by Guyton).

the intermittent character of the flow nor does lengthening the tubing. If the peripheral resistance of the vascular system be imitated by attaching a nipple of small bore to the mouth of the delivery tube so as to increase the resistance to the outflow of fluid, the issuing stream is finer and its velocity is increased but it still remains intermittent (fig. 44, 2). Let the elasticity of the arterial wall now be imitated by replacing the rigid tube by one of rubber, yet let the mouth of the tube be left free and not constricted in any way (fig. 44, 3). The intermittent character of the stream is unaffected. However, if the small-bored nipple representing the peripheral resistance be fixed into the mouth of the elastic tubing the stream will be found to have lost its pulsatile character and to have become continuous (fig. 44, 4). Two factors are therefore necessary to produce

this result, (a) resistance to the outflow and (b) elastic tubing. The reasons for this are clear. If the fluid has free egress from the tube most of that which enters it from the pump is discharged from the open end before the next beat occurs, the pressure, in consequence, does not rise to a sufficient height to distend the rubber wall, i.e., elasticity is not called into play, over-filling of the tube does not occur, and in consequence the latter acts simply as though it were composed of rigid material.

The foregoing facts apply directly to the arterial system. The elasticity of the vascular walls and the peripheral resistance are both essential for the maintenance of the diastolic pressure. As the contents of the ventricle are thrown into the already over-filled system during systole the added pressure which is then exerted upon the vascular walls causes their further distension. After the completion of systole the elastic walls rebound and

FIG. 44. Description in text.

pressing upon the blood within their embrace force it onwards through the peripheral vessels. In other words, the arterial lumen returns to its previous diameter and the energy that had been stored up during the stretching of the elastic tissue is in this way gradually expended during diastole.

It may then be said that the elastic recoil of the arterial wall acts in a sense as a subsidiary pump to drive the blood onwards in a continuous stream between the heart beats. Otherwise the pressure would fall to zero after each systole.

THE INFLUENCE WHICH VARIATIONS IN SOME OF THE FOREGOING FACTORS EXERT UPON THE DIFFERENT PHASES OF THE ARTERIAL PRESSURE

(1) *Change in heart rate unaccompanied by an alteration in any of the other factors, e.g., output of heart per minute (p. 214), peripheral resistance, etc., will cause a change in the diastolic pressure but relatively little change in the systolic.* During cardiac acceleration, for example, the diastolic period is shortened and less time is therefore allowed for the energy stored in the elastic walls during systole to become converted

into energy of flow during diastole. In other words, the fall in pressure during diastole is halted at a higher level by the earlier arrival of the next beat. A decrease in heart rate will have the opposite effect; with the longer diastole the slope of pressure is enabled to reach a lower level. Since the quantity of blood entering the arteries per minute remains constant the quantity entering at each beat must vary inversely with the change in rate, which accounts for the relatively small change in the systolic pressure.

(2) *Alterations in the quantity of blood discharged per minute by the ventricle.* If little change should occur in the heart rate and other factors remain unaltered, increase in the output per beat of the heart causes a rise chiefly of the systolic pressure. The diastolic pressure is raised less noticeably, consequently the pulse pressure is increased. The explanation for the less pronounced rise in the diastolic pressure is that, as a result of the high pressure at the end of the ejection period, the pressure gradient throughout diastole is steeper and more energy is expended in giving velocity to the blood; of the blood pumped into the arterial system during systole a larger proportion than ordinarily will therefore have passed through the arterioles by the end of diastole.

(3) *Changes in the peripheral resistance* while other factors remain constant. Though these affect both systolic and diastolic pressures they show their influence predominantly upon the latter phase. The diastolic period is considerably longer even in a rapidly beating heart than the ejection period of systole (p. 172) and, as we have seen, the peripheral resistance is an important factor in the maintenance of the diastolic pressure. It follows therefore that any increase or decrease in the outflow from the arterial system will affect this pressure to a greater degree than the systolic. The mean pressure and pulse pressure vary accordingly. Aortic regurgitation produces an effect upon diastolic pressure similar to that caused by a reduction in the peripheral resistance but greater in degree. The mechanical principles involved are similar; an increased quantity of blood passes from the arterial system during diastole as a result of leakage through the incompetent aortic valves. The peripheral vessels are also usually dilated, which, combined with the high pulse pressure, may cause the appearance of a pulse in the capillaries especially if their emptying be aided by holding the arm above the heart level. Slight pressure upon a superficial capillary area such as at the base of the finger nail may then show alternate blanching and flushing synchronous with the heart beat (see also p. 271). In aortic regurgitation the pulse pressure attains a magnitude seen in no other condition (80 or 110 mm. Hg) for not only is the diastolic pressure much reduced but the systolic pressure is raised as well, owing to the greater volume of blood ejected at each heart beat—that which has regurgitated through the aortic valves plus that

received from the auricle. Also for these reasons, the carotids throb visibly and the pulse is of the collapsing type (water hammer or Corrigan's pulse) that is, when the subject's wrist is held above the shoulder a short forcible impulse is felt during systole but the pressure is not sustained, and falling precipitately during diastole, leaves the artery empty beneath the finger. A pulse tracing shows a wave of large amplitude with a high sharp systolic peak and a steep diastolic decline. An arterio-venous aneurysm produces similar effects (p. 226) upon the arterial system.

(4) *Changes in blood viscosity*, other factors remaining unchanged, tend to affect the diastolic pressure in a manner similar to changes in the calibers of the peripheral vessels.

(5) *Increase in blood volume* will raise both pressures, as a result of the overfilling of the arterial system and greater stretching of the elastic walls.

(6) *Reduction in elasticity of the arterial walls.* Obviously a condition, such as arteriosclerosis which renders arteries less resilient and more like rigid tubes will tend toward a lowering of diastolic pressure (p. 122). Yet as a matter of fact, in arteriosclerosis the diastolic pressure may be raised rather than lowered, since there is frequently an associated narrowing of the peripheral vessels which more than offsets the hardening of the walls of the larger arteries. When, however, the sclerosis is confined to the larger vessels and their branches while the peripheral vessels are free from proliferative changes which narrow their lumina the diastolic pressure is lowered. Diminished distensibility of the vascular walls tends to increase the systolic pressure.

In the foregoing paragraphs variations in the several blood pressure factors and their effects have each been considered as being the only variable in a particular instance. The object of this was to disclose the value of each and the manner in which it acted. Yet it must be remembered that such a description is more or less artificial and that in health and even to a large extent under pathological conditions the various factors interact with one another—there is a give and take among them. When a change in the value of one factor occurs, readjustments of others take place to regulate the blood pressure and keep it within the normal limits. For instance, dilatation of the vessels in one area may be accompanied by vasoconstriction in another (p. 246). Reduction in blood volume as by hemorrhage, is followed by constriction of the peripheral vessels (p. 22), while increased blood volume or a rise in viscosity will likely be followed by the opposite effect upon the vessels.

CHAPTER XVI

THE BLOOD PRESSURE IN THE HUMAN SUBJECT

METHODS OF MEASUREMENT. THE VENOUS BLOOD FLOW

It is evident that any method for the measurement of the human blood pressure must be indirect. The principle employed consists in balancing air pressure against the pressure of the blood in the brachial artery and then estimating the former by means of a mercury or an aneroid manometer.

The instrument used for this purpose includes a flat rubber bag covered by an undistensible envelope of cotton fabric. The cavity of the bag is connected by a length of rubber tubing with the manometer and by another tube with a hand bulb or small pump. By this means the bag can be inflated to any desired pressure. A small valve between the bulb or pump and the bag permits the escape of air, and the reduction of the pressure as required. The uninflated rubber bag (usually referred to as the cuff or armlet) which should be at least 12 cm. wide is wrapped snugly around the upper arm just above the elbow. The bag is then inflated until the air pressure within it overcomes the arterial pressure and obliterates the arterial lumen. The pressure is increased a little beyond this point and is then cautiously reduced again,¹ by the release of the valve, until the arterial pressure just overcomes the air pressure and blood escapes beyond the cuff into the peripheral section of the artery. At this instant the pressure in the bag is read from the manometer. Since the air pressure practically balances the systolic arterial pressure the manometer reading must indicate the value of the latter. It is essential to the method that the manometer reading be taken at the instant when the blood escapes beneath the cuff.

One of two methods, the *palpatory* or the *auscultatory*, may be employed to determine the latter.

(1) *The palpatory method.* In this method the examiner takes the moment that the pulse is felt at the wrist as the index of the systolic pressure. This method is now rarely used since it lacks accuracy. It assumes that the first escape of blood beneath the cuff will cause pulsation in the peripheral artery, but there is no evidence that the amount of blood which escapes beneath

Should deflation be carried out too rapidly the mercurial type of clinical manometer shows a considerable lag, due to the time required for the air above the mercury column to reach atmospheric pressure. The rate of deflation should not exceed from 2 to 3 mm. Hg per second.

the cuff when the artery first opens is sufficient to produce a pulse wave detectable by the finger. Definite pulsation may not occur until the cuff pressure has been lowered 5 to 10 mm. below the point when the artery first becomes pervious. This method therefore gives readings that are too low. Another disadvantage of the palpatory method is that the diastolic pressure cannot be measured satisfactorily.

THE AUSCULTATORY METHOD

In this method, which was introduced in 1905 by the Russian physician Korotkow, certain sounds heard during auscultation of the brachial artery below the cuff are employed as the criteria for the systolic and diastolic pressures. Under ordinary circumstances if a stethoscope be placed upon the brachial or any other artery, no sound can be heard, the flow of blood along the arterial channels being inaudible. If however the artery be compressed by the manometer cuff so as to completely arrest the flow of blood for a moment, a sharp light tapping sound in rhythm with the heart beat will be heard when the pressure in the cuff is again released and falls just sufficiently to permit the arterial lumen to open and allow a jet of blood to pass beyond. As the pressure in the cuff is progressively lowered the sound undergoes a series of changes in quality and intensity.

Four phases of the sound, each having its distinctive character may be heard in succession, in the normal individual, as the pressure is gradually reduced from about 120 to 80 mm. of mercury or less. These are given below with the average pressures at which they are normally heard:

Sounds of Korotkow

- | | |
|------------|---|
| Phase I. | Sudden appearance of a clear, but often faint, tapping sound growing louder during the succeeding 10 mm. Hg fall in pressure. |
| Phase II. | The sound takes on a murmurish quality during the next 15 mm. fall in pressure. |
| Phase III. | Sound changes little in quality but becomes clearer and louder during the next 15 mm. fall in pressure. |
| Phase IV. | Muffled quality lasting throughout the next 5 to 6 mm. Hg fall. After this all sound disappears. |

The beginning of the first sound is taken as the *index of systolic pressure*. As it is quite faint at its commencement it may not be caught at its first appearance by the ear of the inexperienced, or if the observer's hearing is distracted by other sounds. The sound then will not be picked up until the pressure has dropped below the level at which it could be heard in quiet surroundings and the blood pressure reading will be too low.

The fourth sound just before its complete disappearance is taken as the *index of the diastolic pressure*. This sound coincides with the moment that the blood escapes beneath the armlet in a continuous stream rather than intermittently.

The measurement of blood pressure in man is attended by certain inaccuracies dependent upon the resistance of the tissues of the part and, under certain conditions, of the arterial wall itself to the compressing force. These fallacies are to a large extent mitigated by the use of a broad armlet (12 cm. in width), as first introduced by von Recklinghausen, which distributes the applied pressure over a wide area. In a person with normal arterial walls the pressure as measured is probably very close to the true systolic pressure. Variations in the resistance of the arterial wall in different individuals as a result of sclerotic changes or simple hypertonus of the muscular coat may lead to error and give readings that are too high. Repeated compression and decompression just before the actual determination is made will, as a rule, soften the artery or remove the spasm of its walls sufficiently to eliminate this source of inaccuracy. Even when definite arteriosclerosis exists approximately correct estimations of the blood pressure are obtained when this precaution is taken. Though lower readings as a rule are not obtained in a normal individual by repeated readings, in others with apparently normal arteries the reading obtained after the third or fourth trial may as a result of the reduction in tone of the vessel wall be lower by several millimeters than the initial observation.

RELATIVE VALUES OF SYSTOLIC AND DIASTOLIC MEASUREMENTS

The systolic pressure is subject to wider variations under ordinary conditions of health than the diastolic, it also varies more with local arterial changes; for these reasons less reliance can be placed upon it than upon the diastolic. A knowledge of the diastolic level is also of greater value for other reasons. (1) It represents the constant load which the vascular walls are carrying, not only in the larger arteries but throughout the arterial system, for it will be recalled that the fall in systolic pressure from the large to the small arteries is considerable, whereas the diastolic shows

comparatively little change. (2) It also reflects more accurately the state of the peripheral vessels for as already pointed out (p. 124) the systolic pressure responds less to variations in the peripheral resistance.

THE RELATION OF THE PULSE PRESSURE TO THE CARDIAC OUTPUT

The pulse pressure, other factors remaining the same, varies with the amount of blood ejected into the aorta per beat, and we know that the work of the heart depends chiefly upon the amount of blood ejected per minute against the mean pressure in the aorta. It follows therefore that provided the peripheral resistance, blood viscosity and other factors concerned in the maintenance of blood pressure remained constant the product of pulse pressure and heart rate ($PP \times HR$) might be used as an index of the energy of the ventricular contraction. Erlanger and Hooker found that the product tended to remain constant under ordinary physiological conditions, which would not be expected to alter the cardiac output, an increase or decrease in heart rate occurring to compensate for changes in pulse pressure. The index in an individual having the usual pulse pressure of 40 and a pulse rate of 72, would be $(40 \times 72 =) 2880$. Conditions causing a pronounced rise or fall in the cardiac output, on the other hand, are accompanied by a corresponding change in the product. The index has therefore been used as a rough clinical gauge of the minute volume of the heart, and so as a guide to the manner in which the heart is performing its work in diseased states. The index may be of value in following the course of an individual case if the observations are made at comparatively short intervals and the conditions to which the patient is exposed remain practically the same from one observation to the next. No absolute or quantitative value can, however, be attached to it, nor can the results obtained in different individuals be compared with one another.

Miss Skellern has endeavored by means of animal experiments, using the heart lung preparation, to determine the practical value of this index. She could find no constant relationship between the cardiac output and the product of pulse pressure and pulse rate, concluded therefore that no reliance could be placed upon it. The ratio of the index to the output varied from 6.5 to 47. Her results show, however, that in a given experiment in which the peripheral resistance was kept constant the disagreement was not nearly so great as this, and that the index and the output were altered in the same direction. That is, an increase in output was followed by a rise in the value of the index and vice versa. That, as a matter of fact, is practically all that has been claimed for the test. It is considered only as a means of arriving at a general idea of improvement or otherwise occurring in cardiac behavior during the course of an illness. Bearing in mind its limitations, and the restrictions based upon its use

its value may be conceded. *Asperly and Cary* data for regarding the P/P (brachial) $\times P/R$ as a index of the blood flow through the arm.

THE NORMAL ARTERIAL BLOOD PRESSURE

The average systolic pressure of young male is usually given as 120 mm. Hg; the diastolic 80, the mean pressure as 93 and the pulse pressure as 40. The pulse pressure is therefore half of the diastolic and one-third of the systolic, and the normal ratio of systolic, diastolic, pulse pressures is 3-2-1. This ratio holds only at these levels, being altered if the pressures are much above or below the foregoing figures. *Robinson and Brucer* conclude from a study of nearly 1100 persons that the range of normal blood pressures is from 90 to 120 mm. Hg systolic and 60 to 80 mm. Hg diastolic. They contend that blood pressures above the upper levels just mentioned cannot be considered as normal at any age. Slight diurnal variations in blood pressure of from 5 to 10 mm. Hg systolic occur, the peak being in the afternoon and the lowest level in the early hours of the morning.

VARIATIONS IN THE BLOOD PRESSURE UNDER PHYSIOLOGICAL CONDITIONS

Age, sex, and build

Age exerts a definite influence upon the blood pressure levels. At birth the systolic pressure measures from 20 to 60 mm. with an average of 40 mm. It rises rapidly, however, and has an average value of about 70 mm. at the end of a fortnight and 80 mm. at the end of a month. A slow steady rise takes place from this time until about the twelfth year when it averages 105 mm. With the onset of puberty a more sudden rise occurs, which in boys, reaches 120 mm. at about the age of 17. In girls, there is an increase in systolic pressure to the fifteenth year, then a decline to the eighteenth; it remains fairly steady from then on or shows a gradual rise. It has usually been considered that a steady though not great rise in blood pressure from adolescence to old age is the rule in health; the averages for the age of 60 being given as about 140 systolic pressure and 87 diastolic. In men, it is usually stated that a rise of about 0.5 mm. in the systolic and 0.2 mm. in the diastolic and pulse pressure occurs for each year of age after 20 (see table 15) but, from the observations of *Robinson and Brucer*, mentioned above, it is debatable whether this increase with age can be considered to be a physi-

ological or normal phenomenon. In women up to the time of the menopause the systolic pressure is from 4 to 5 mm. lower than for men of the same age. At the menopause, however, there is a somewhat abrupt rise and the pressure remains a little above the male average from then onwards.

Symonds and others have found a correlation between the systolic pressure and obesity. Comparing groups of overweight and normal individuals the former were found to have a pressure on the average 7.5 mm. higher than the latter. In markedly obese but otherwise healthy persons the difference was even more pronounced. The incidence of abnormally high blood pressure (hypertension) is also definitely greater in persons of overweight.

Robinson and Brucer claim that body build is correlated with the blood pressure level. They found in an examination of a large number of persons that in any weight group broad-chested persons on the average had a higher blood pressure (both systolic and diastolic) than had those of slender build.

The effects of digestion, emotion, exercise and posture

Digestion. The systolic pressure is influenced to a small but definite extent by meals. A rise of from 6 to 8 mm. is the usual effect, and this lasts for an hour or so. There is little change in the diastolic pressure. If anything it is reduced, presumably a result of vasodilation in the digestive organs and splanchnic.

Emotional Influences, excitement, fear, worry, etc. markedly affect the arterial blood pressure, especially the systolic. The effects are brought about through increased cardiac action and changes in the state of the vessels through impulses playing upon the cardiac and vasomotor centers in the medulla. The liberation of adrenaline into the blood stream may also be a factor. Quiet restful sleep, according to *MacWilliam*, is accompanied by a fall of from 15 to 30 mm. in the systolic pressure. The fall is most marked during the first hours, rising gradually again after this until the time of waking. *MacWilliam* observed that if the sleep was disturbed and accompanied by imaginary motor activities there might be no depression of the pressure, but rather an elevation, in some instances to as high as 200 mm. systolic and 105 mm. diastolic.

EXERCISE. Of all physiological conditions this, if of a strenuous nature, has the most powerful effect upon the arterial blood pressure. During the muscular effort or even immediately before,

i.e., at the instant that the exertion is contemplated, the pressure commences to rise and reaches a height of 180 or 200 mm. The diastolic pressure shows a less pronounced rise (100 to 110) so that the pulse pressure is increased. In light exercise the diastolic pressure may remain at the normal level while the systolic rises several millimeters. Immediately after the exercise the pressure drops momentarily to normal or even slightly below. It then mounts rapidly to its previous high level, from which it gradually declines again, and in a healthy person reaches the normal within from 1 to 4½ minutes. The evanescent drop in pressure is explained by Cotton, Lewis and Rapport as being due to the sudden relaxation of the abdominal muscles. The blood is drained into the

TABLE 15
The average variations of blood pressure (after Hunter's compilation of observations on a quarter million healthy Americans)
(After Gager)

AGE	SYSTOLIC PRESSURE	DIASTOLIC PRESSURE	PULSE PRESSURE
10	103	70	33
15	113	75	38

45	128	85	43
50	130	86	44
55	132	87	45
60	135	89	46

venous reservoirs. These when deprived of their support (abdominal muscles) have their capacity increased and the blood flow into the right heart is temporarily reduced. It is not until an appreciable time has elapsed to enable the increased venous capacity to become filled again by blood pouring in from the recently active muscles that an adequate flow into the right heart is restored (p. 130). These responses are much more pronounced and the final decline of pressure to normal levels is postponed if the exercise is carried out in a rarefied atmosphere, or if a condition of "irritable heart" exists.

POSTURE. The diastolic pressure is somewhat higher in the standing than in the sitting position and lowest in recumbency. This change is found to occur whether the postural change is brought about actively or passively and is evidently an

over-compensation for the gravity effect (p. 138). The systolic pressure usually rises but to a less extent than the diastolic, so the pulse pressure is reduced. Reverting from the standing to the sitting or recumbent position has the reverse effect: fall in diastolic pressure and rise in pulse pressure. In persons with an abnormally and habitually low blood pressure, the systolic pressure may actually rise in the lying-down position and fall when the subject stands. The diastolic, on the other hand, is always lowered in recumbency and raised in the erect posture.

PATHOLOGICAL VARIATIONS IN THE ARTERIAL BLOOD PRESSURE

The blood pressure may be persistently above or below the normal range. These departures from the normal are termed *hypertension* or *hypotension*, respectively. It is difficult to make a sharp separation of the normal from the abnormal but an elevation above the average normal for particular age, of 15 mm. in the systolic and 8 mm. in the diastolic may be considered to be definitely abnormal. A reduction below 110 mm. in an adult male (or 100 mm. in adult female) of any age is usually termed hypotension.

ARTERIAL HYPERTENSION

A high blood pressure accompanies such conditions as increased intracranial pressure, *hypothyroidism* and *adrenal tumor or hyperplasia* (p. 691). In these, the hypertension is more or less incidental or of subordinate importance to the primary disease. In the first of these conditions the heightened pressure is apparently due to generalized vasoconstriction resulting from reduced oxygen supply to the vaso-motor center (p. 292). Cushing pointed out that the increased pressure within the cranial cavity caused compression of and slowing of the blood flow through the vessels supplying the medulla. In animals also, a pronounced rise in blood pressure may be induced by *asphyxia* (p. 248), the increased hydrogen ion concentration of the blood acting as stimulus to the vaso-motor center. Permanent hypertension has been produced by the injection of an inert substance such as kaolin into the *arteria magna of rabbits* (Dixon and Heller) thus interfering with the blood supply to medullary centers, and cerebral anemia produced by ligation of the carotids and vertebrals in *hypertension in the dog*. In *hyperthyroidism* hypertension is associated with an increased cardiac output. Temporary rises in blood pressure

in attacks of *angina pectoris*, in *lead colic* and the *crises of tabes*. The hypertension associated with adrenal tumor or hyperplasia is usually paroxysmal character and is due to liberation of excessive amounts of adrenaline (p. 691).

The types of hypertension under consideration in this section are (1) that *secondary to renal disease*, and (2) *essential or primary hypertension*.

1) *Hypertension secondary to renal disease*.—Earlier or later in chronic glomerulo-nephritis the general blood pressure rises, the left ventricle hypertrophies and the arterial tree shows degenerative changes (atherosclerosis).

ETIOGENESIS. It is a well attested fact that in some forms of the disease as well as in primary essential hypertension increased peripheral resistance is the immediate causative factor. The increased resistance is mainly in the splanchnic (Abramson). None of the other factors which have been enumerated in the last chapter maintaining the normal blood pressure exerts an excessive influence in these hypertensive states. The hypertrophy of the heart, for example, is merely secondary—a physiological compensation rendered necessary, as first suggested by Richard Bright (1827), by the greater resistance offered to the flow of blood through the peripheral vessels. Divergent views have been held as to the manner in which the increased peripheral resistance is brought about. Of the theories which have been proposed two require some mention. A brief account will serve as a background to a description of modern researches upon the subject.

(a) *Reduction in size of the vascular bed of the kidney* as a result of structural narrowing of the renal arterioles and the destruction of large numbers of glomerular capillaries. Such changes, it was presumed, would narrow the outlet from the arterial to the venous system. There is no evidence that a localized increase in peripheral resistance of this nature is responsible for hypertension, for in most animals (but excepted) removal of a kidney and part of the other has little or no effect on the blood pressure. Anderson reduced the renal mass in rabbits to the point where severe renal insufficiency resulted without causing any rise in blood pressure. From the great adaptability of the circulation this is what one should be led to expect, the removal of a vascular area from one part of the body being readily compensated for by the opening of collateral channels elsewhere.

(b) *The extension within the circulation of a specific substance produced by the kidney.* Tigerstedt and Bergquist (1918) obtained a pressor substance from normal kidney tissue of rabbits. They postulated that deterioration of this material in kidney disease and its

accumulation in the circulation was responsible for a generalized vasoconstriction. The fact that renal insufficiency caused by the removal of kidney tissue is not productive of hypertension is in harmony with such a theory, for the production of a pressor substance would also be reduced by the operation. On the other hand, Goetz and Dragstedt found that animals in which the urine had been diverted into the terminal ileum or directly into the blood showed no elevation of blood pressure, though they were observed for periods ranging from 11 days to 5 weeks. Yet, as will be seen presently, the conclusions of Tigerstedt and Bergquist came remarkably close to the modern conception of the production of hypertension in renal disease.

THE PRODUCTION OF HYPERTENSION BY REDUCING THE BLOOD FLOW THROUGH THE KIDNEY

Though others had reported that compression of the renal arteries in animals caused a rise in blood pressure, Goldblatt and his associates were the first to show that this procedure causes consistently pronounced and permanent hypertension. Constriction of the renal artery is effected by means of a specially devised adjustable silver clamp. Ischemia of one kidney, produced in this way, the other remaining intact, causes a moderate elevation of the blood pressure which commences three or four days after the operation, but persists for only a short time, returning to the normal level after a month or so. If, on the other hand, both renal arteries are constricted or if one alone is clamped and the opposite kidney removed, permanent hypertension results. The severity of the hypertension varies with the degree to which the renal blood flow has been curtailed. Unless the compression of the renal artery is extreme and, in consequence, the ischemia of the kidney very severe, the elevation of the blood pressure is not accompanied by any detectable impairment of renal function and the kidney shows little histological change. But with severe constriction of the artery, renal insufficiency develops and the animal may die in uremia.¹ The

¹ Hypertension has also been produced by partial obstruction of the ureters, or by renal tumors caused by exposure of the kidneys to X-rays or by the injection of a nephrotoxic agent such as uric acid. On the other hand, the production of multiple aneurysms in the renal vessels, as by injections of liquid paraffin or carbon particles, is not followed by elevation of the blood pressure. Hypertension also follows constriction of the aorta above the origins of the renal arteries. Page found that hypertension develops within four to six weeks after a kidney has been wrapped loosely in cellophane or silk. These coverings set up a chronic inflammatory reaction (peritonitis) which results in the formation of a firm fibrocartilaginous capsule enclosing the kidney. The hypertension is the result, appar-

hypertension and renal failure are accompanied by widespread degenerative changes in the systemic arterioles, the arteriolar walls in many instances showing hyaline degeneration and necrosis. Such a state of the vascular system, taken together with renal insufficiency and the elevated blood pressure, is closely comparable to malignant hypertension as seen clinically (p. 136). Goldblatt was unable to produce arteriolar degeneration in the kidney itself for the simple reasons that, (a) a severe degree of hypertension could not be produced as long as one non-ischemic kidney remained in place, and (b) the vessels of the ischemic kidney are protected from the destructive effect of the hypertension by the compressing clamp, i.e., they lie within a region of low pressure. Wilson and Byrom have succeeded, however, in producing severe hypertension (up to 260 mm. Hg) in rats by constricting one renal artery and leaving the opposite kidney *in situ*. Severe vascular damage, consisting of hyaline or fibrinoid degeneration and necrosis of the walls of the arterioles of the intact kidney (especially of the afferent glomerular vessels) as well as of the systemic vessels, was observed. There was no definite evidence that renal insufficiency played a part in the production of the vascular lesions, though renal failure occurred ultimately as a consequence of the arteriolar damage.

THE MECHANISM INVOLVED IN THE PRODUCTION OF HYPERTENSION BY RENAL ISCHEMIA. It has been definitely established that the hypertension produced by hindering the blood supply to the kidney is due to a vasoconstrictor (pressor) substance produced in the ischemic organ. The hypertensive effect is not dependent upon nervous mechanisms (e.g., a reflex through afferent endings in the kidney, the vasomotor center and vasoconstrictor fibers to the systemic vessels) for it occurs after denervation of the kidney, or section of the splanchnic nerves or of the anterior spinal nerve roots. Even complete excision of the sympathetic chains or destruction of the spinal cord does not prevent the development of hypertension nor materially alter its course after it has been established. Furthermore, hypertension results if

ently, of the renal ischemia induced by the compression of the vessels within the kidney by the newly formed tissue. Contemporaneously and independently, Greenwood, Nassim and Taylor observed that if one kidney was surrounded by a closely fitting cast of gauze stiffened by impregnation with collodion, hypertension occurred *within a few hours after the removal of the opposite kidney* and persisted indefinitely. No rise occurs as long as the other kidney remains undisturbed.

one kidney which has been transplanted into the inguinal region or into the neck (renal artery to carotid, renal vein to jugular) is made ischemic and the other kidney then excised. The transplanted kidney is, of course, completely isolated from nervous control. The inability of such denervation operations to prevent or modify the hypertensive effect proves conclusively that it is mediated through a pressor substance circulating in the blood stream and, further, that the latter acts, not through the vasomotor center, but either directly upon the peripheral vessels or through the intermediary of one or other of the endocrine organs (see below). The substance formed in the ischemic kidney which is responsible for the hypertensive effect is called *renin*, the name already mentioned as having been originally used by Tigerstedt and Bergman. Renin itself, as we shall see presently, is free from any pressor action. It is an enzyme. It is non-dialyzable and thermolabile being destroyed above 56°C. Its substrate (see angiotonin precursor, below) is also thermolabile and is probably a pseudoglobulin.

Difficulty has been experienced in demonstrating in a direct way the presence of a pressor substance in the circulation of the hypertensive animal. The blood pressure of a normal dog is not elevated by transfusing it with the blood of one with renal hypertension. Extracts of ischemic kidneys have yielded uncertain results, for renin is present in the normal kidney though in somewhat smaller amounts it is claimed, than in the ischemic organ. Transfusion and crossed circulation experiments have yielded conflicting results. Katz and his colleagues transfused non-hypertensive nephrectomized dogs with the blood of hypertensive animals over a period of 18 hours but observed no rise in the blood pressure of the recipient animals. On the other hand, Solandt, Nassim and Cowan have reported that when by means of a specially designed pump large volumes of blood were transfused from a hypertensive to a non-hypertensive nephrectomized animal, a temporary rise in blood pressure resulted.

Nevertheless, important evidence of the production of a vasoconstrictor substance in the ischemic kidney has been furnished by the experiments of Houssay, Fasciolo and Taquini. They found that the blood pressure of a non-hypertensive, nephrectomized animal was raised when the ischemic kidney of a hypertensive animal was transplanted into its neck, whereas the transplantation of the kidney of a normal animal gave a

negative result. They also showed that the plasma of blood collected from the vein of an ischemic kidney, as compared with that from a normal one, was markedly vasoconstrictor when perfused through the vessels of the toad.

Renin has also been found in the circulation of hypertensive patients and in the blood of animals with renal hypertension. A rise in the concentration of renin in the blood has been observed in animals suffering from surgical shock, following hemorrhage and in other states associated with a profound fall in blood pressure. Such observations suggest very strongly that the liberation of renin by the normal kidney is a factor in the regulation of the blood pressure, aiding in its restoration to higher levels when it becomes greatly lowered.

THE ACTIVE VASOCONSTRICTOR AGENT. Helmer and Page found that the more purified preparations of renin were inactive. When perfused with Ringer's solution through the vessels of an isolated organ such as the rabbit's ear or dog's tail, such preparations showed little or no vasoconstrictor action. The addition of plasma, blood or serum globulin to the purified renin preparation restored its vasoconstrictor property. Blood or plasma, therefore, contains a material which Helmer and Page originally called renin activator but is now referred to as *angiotonin precursor* and is believed to be a pseudoglobulin. The active vasoconstrictor substance itself i.e., the product of the action of renin upon the serum globulin is called *angiotonin*.³ Angiotonin has been isolated in crystalline form; it is heat stable and dialyzable. The hypertensive action of renin becomes less pronounced with successive injections. This tolerance to repeated injections of renin has been termed *tachyphylaxis*. The phenomenon is attributed by Page and his associates to the exhaustion of angiotonin precursor. The serum globulin (angiotonin precursor) is in low concentration in the plasma and is produced, apparently, in the liver since it disappears from the blood after hepatectomy. It is said to be increased in experimental hypertension and in clinical essential hypertension. Angiotonin exerts its constrictor action directly upon the minute systemic vessels. It reduces the renal

blood flow as a result, presumably, of constriction of the efferent glomerular vessels, which leads in turn to an increased filtration rate (p. 387). It does not increase the cardiac output.

Bing and Zucker believe that a pressor substance other than renin, namely, *hydroxytyramine*, is formed in the acutely ischemic kidney by the decarboxylation of l-dihydroxyphenylalanine. This latter, or l-dopa—as it is briefly designated—has no hypertensive action itself but when perfused through the excised ischemic kidney, but not through one with an adequate blood supply, forms the pressor amine *hydroxytyramine*. Also, when l-dopa is injected into the substance of a kidney rendered completely ischemic by clamping its pedicle and the clamp then released, a rise in blood pressure (of from 15 to 115 mm. Hg) occurs 3 hours or so later. On the other hand, when the circulation is restored to a completely ischemic kidney that has *not* been injected with l-dopa no rise in blood pressure occurs, unless the period of circulatory arrest is much longer than that cited in the previous experiment. The effect of *tyrosinase*—a phenolic oxidase—lends support to the idea just outlined of a pressor amine being the responsible agent in renal hypertension. This enzyme, as shown by Schroeder and Adams, lowers the blood pressure of animals suffering from the hypertension caused by renal ischemia and has the power to inactivate renin, adrenaline and tyramine *in vitro*. An amino-oxidase has also been prepared from hog liver, which, according to Schroeder, lowers the blood pressure of hypertensive patients and of dogs.

Raska has compared the enzymatic activity of slices of ischemic kidney tissue from hypertensive dogs with that of normal kidney tissue. The oxygen consumption of the ischemic tissue was found to be much below normal. Extracts were also prepared from ischemic kidneys and tested for their enzymatic activity (amino-acid oxidase, amine oxidase, and polyphenol oxidase activity) by measuring the oxygen consumption and ammonia production when tyramine, iso-amylamine, *dl*-alanine and *l*-aspartic acid were used as substrates. The activity of such extracts was found to be considerably less than that of extracts of normal kidneys.

Certain amino-acids after decarboxylation without deamination (p. 507) yield powerful pressor amines. An amino-acid carboxylase which acts under anaerobic conditions has been demonstrated in the kidney by Holtz and his associates. This observation combined with Raska's results and those of Bing and Zucker suggest that excessive amounts of pressor amines may be produced by the ischemic kidney as a result of an increase of anaerobic carboxylase activity and depression of oxidative enzymatic processes, and that such may be responsible, in part, for the hypertension following constriction of the renal artery. But there are several reasons for believing that they do not play a primary or dominant rôle either in experimental hyper-

³ Braun-Menendez and his associates have given the name *hypertensin* to the vasoconstrictor substance formed by the enzymatic action of renin upon the globulin of the serum, which they call *hypertensin precursor*. Hypertensin, therefore, corresponds to angiotonin and hypertensin precursor, to angiotonin precursor.

tension or in clinical essential hypertension. Among the observations which may be cited in argument against pressor amines playing an important part in the development of hypertension are, that the ischemic kidney does not suffer from anoxia and that decarboxylase is absent from the kidney of the rat, an animal in which renal hypertension is readily produced.

THE SOURCE OF RENIN AND THE ADEQUATE STIMULUS FOR ITS LIBERATION. Renin is confined to the cortex of the kidney. It is produced, or stored, apparently, by the proximal convoluted tubules and not by the juxtaglomerular (p. 379) apparatus as was previously supposed. Kidneys, in which the cells of the proximal convoluted tubules have been destroyed by poisoning with tartrate do not contain renin.

The stimulus for the production or liberation of renin by the kidney is not known. Ischemia does not appear to be directly responsible, for the immediate effect of constriction of the renal artery is dilatation of the renal vessels, the normal blood flow through the kidney being maintained. Anoxia of the renal tissue does not appear to be a necessary condition for the development of renal hypertension, because no increase over the normal occurs in the arterio-venous oxygen difference of the ischemic kidney (Levy and associates). On the other hand, anoxia induced by cyanide does not cause renin to appear in the circulation although a kidney so poisoned produces renin when the renal artery is clamped. Corcoran and Page, and Kohlstadt and Page believe that *reduction in pulse pressure in the renal vessels is the adequate stimulus*. They constricted the artery of a perfused kidney while normal blood flow and mean blood pressure in the vessels distal to the constriction were maintained. A reduction in pulse pressure in the renal artery distal to the constricting clamp was followed by the appearance of renin in the renal vein. Reduction in renal blood flow occurred only as a late effect.

It has been mentioned that ischemia of one kidney without interference with the kidney of the opposite side is not followed by permanent hypertension nor is the elevation of blood pressure, even while it lasts, as great if a normal kidney is present, and the return of the blood pressure to normal after excision of an ischemic kidney is much less rapid if the opposite kidney is also removed. Also, in order to demonstrate the maximum effect of the pressor substance liberated by the ischemic kidney the recipient animal must first be nephrectomized. All these facts suggested that normal

renal tissue elaborated a substance inhibiting the action of the pressor agent.

Braun-Menendez and his associates demonstrated the presence in normal kidney tissue of an enzyme which inactivates the pressor principle (angiotonin). This enzyme called *angiotonase* by Page and *hypertensinase* by its discoverers, is possibly responsible for the effect exerted by normal kidney tissue upon the development and severity of renal hypertension. Attempts to obtain a material from extracts of normal kidney tissue which would neutralize or inactivate the pressor substance responsible for clinical hypertension have not been very successful. Nevertheless, such an agent has been prepared by Grollman, Harrison and Williams and by Page and his associates which is stated to cause a pronounced amelioration of the hypertension due to renal ischemia, but is without effect upon the normal blood pressure or upon hypertension due to other causes.

THE ENDOCRINES IN RELATION TO EXPERIMENTAL HYPERTENSION. Though the evidence points to the hypertensive substance as acting directly upon the vessels, the possibility must be considered that it exerts its effect by stimulating a ductless gland, such as the pituitary or adrenal, to secrete a vasoconstrictor substance. That the adrenal medulla plays a rôle in this respect can be summarily dismissed, for the hypertension is not prevented or modified in any way by bilateral excision of all medullary tissue. On the other hand, Goldblatt has found that constriction of the renal arteries fails to cause a rise in blood pressure after bilateral removal of the adrenal cortex, even though the animal is maintained in good condition by a high salt and low potassium diet (p. 694). But if cortin is administered to the adrenalectomized animals, renal ischemia is followed by the usual hypertensive response. The blood pressure of hypertensive rats is lowered by adrenalectomy and is only partially restored by the administration of *desoxycorticosterone*. However, these results should not be taken to imply that the renal principle mediates its action *through* the adrenal cortex, for Houssay and his colleagues found that in short term experiments in which an ischemic kidney was transplanted into a non-hypertensive animal, complete adrenalectomy of the latter or ligation of the adrenal veins did not prevent the rise in blood pressure. These two sets of experimental results have been reconciled by the observation that angiotonin precursor is reduced after adrenalectomy. The cortical hormone appears to

be necessary, therefore, for the production of the substrate upon which renin acts. There is no evidence of the pituitary playing a rôle in the production of renal hypertension. So far as is known, the thyroid is not implicated in any way in its development.

THE SIGNIFICANCE OF THE RESULTS OF RENAL ISCHEMIA IN EXPERIMENTAL ANIMALS TO THE HYPERTENSION OF CHRONIC RENAL DISEASE. The immense importance of the experimental work which has been outlined in the foregoing sections and its bearing upon the hypertension secondary to renal disease requires no emphasis. Direct proof that reduction in the renal blood flow is the cause of the clinical condition and that a vasoconstrictor substance is elaborated in the diseased kidney as in the ischemic kidney of experimental animals is, of course, very difficult to obtain. But the experimental results are so clear cut that one is forced to the belief that the mechanisms in the experimental and clinical conditions are fundamentally the same. In chronic nephritis the vascular changes within the kidney undoubtedly can reduce the renal blood flow as effectively as compression of the renal artery. The increased peripheral resistance in chronic nephritis appears also to be of non-nervous origin. Pickering comes to this conclusion from his observations upon the cutaneous blood flow of patients. He found that in those with chronic nephritis and hypertension, warming the body (which inhibits vasoconstrictor tone of nervous origin) causes an increase in the blood flow through the hands, as determined by Stewart's method (p. 149), to a degree which falls far short of expectation were vasoconstrictor impulses alone responsible—an indication that some abnormal vasoconstrictor influence persists. Several clinical observations can be cited which stress the cogent argument offered by the experimental results in explaining the hypertension of renal disease. For example, in unilateral renal lesions, e.g., pyelonephritis, associated with hypertension, removal of the diseased organ is followed by the rapid return of the blood pressure to normal levels.

The experiments also carry important physiological implications or at least bring up some interesting questions. Does the pressor substance serve as a physiological mediator of renal blood flow? Is it in the nature of a humor or hormone liberated from the renal cells or produced by them when the functional demands upon the kidney call for a greater blood flow through its vessels? A rôle of this nature is suggested by an experiment performed by Drury. A loop of silk

thread slightly larger than the renal artery was tied around the vessel of one side in young, growing rabbits. As the animals grew the renal artery increased in size until it reached the diameter of the loop which from then on prevented the renal blood flow from increasing to meet the demands of the growing body. The opposite kidney made up for the deficiency by enlarging enormously and as long as it remained undisturbed the blood pressure did not rise. But removal of the hypertrophied kidney was followed by hypertension (up to 200 mm. Hg). An observation reported by Dill and Erickson points in the same direction, namely, that the vasopressor substance serves to proportion the blood flow through the kidney to the demands made upon renal function. The renal arteries on both sides were moderately compressed in a series of pregnant dogs. The operation was followed in from 48 to 120 hours by hypertension, nitrogen retention and hematuria. The animals had convulsive seizures and died in from 3 to 15 days in coma. Lesions in the liver, e.g., periportal necrosis, similar to those found in eclampsia were found at autopsy. Non-pregnant dogs whose kidneys were subjected to the same degree of ischemia, though they developed hypertension, remained in good health.

Hypertension occurs in *acute nephritis*, but the investigations of Pickering indicate that the mechanism of its production is not the same as in chronic nephritis. In the former disease vasoconstriction is apparently of nervous origin, for anesthetization of the ulnar nerve increased markedly the blood flow through the hand, leaving no abnormal vasoconstrictor influence. The hypertension of acute nephritis produced in rabbits by injections of sodium oxalate is also apparently of nervous origin, for Arnott and Kellar found that it is prevented by denervation of the kidney.

(2) *Primary, benign or essential hypertension (hyperpiesia)*

The immediate cause of the raised pressure in this as in the preceding type is an increase in the peripheral resistance, i.e., vasoconstriction or narrowing in some way of the peripheral vessels. It is not due to an increase in any of the other factors upon which the maintenance of the normal blood pressure depends, namely, the output of the heart, the viscosity⁴ or the volume of the blood. The calibers of the retinal arterioles are greatly nar-

⁴ A moderate increase in blood viscosity has been demonstrated in hypertension but it is a contributory cause and probably secondary rather than basic.

rowed, appearing upon ophthalmoscopic examination like silver wires. The state of these vessels may be taken as representative of that of the cerebral vessels and probably of the state of the peripheral vessels generally throughout the body.

The systolic and diastolic pressures are elevated equally, or the systolic to a greater degree than the diastolic; 250 mm. is not an unusual figure for the former and 130 mm. for the latter. In other cases, usually those in an advanced stage, the diastolic pressure is proportionately greater than the systolic, and the pulse pressure reduced. The pressure in the pulmonary circuit is believed to be normal. The pressure of the cerebrospinal fluid is increased in proportion to the rise in the diastolic pressure.

The pressure in the capillaries and small veins is within normal limits, and the slope of pressure through these vessels is not materially different from that in health. But the fall in pressure through the arterioles is much greater than in health (fig. 45). Ellis and Weiss found mean pressures of 155 and 12 mm. respectively in the brachial artery and in the capillaries—a fall of over 140 mm. Of this about 125 mm. must have occurred in the arterioles. Normally the fall of pressure in the latter vessels is about half this figure (approximately 60 mm.).

The high pressure in the arterial system, which of course must be overcome by the left ventricle before it can expel its contents, increases the work of the heart by from 40 to 50 per cent. The ventricular cavity becomes dilated and its walls hypertrophied. The cardiac output, except when the circulation is failing, is normal or only slightly reduced. In certain instances, according to some observers, it is increased. The vascular system, including the renal arterioles, in time suffers degenerative changes (p. 135) and renal insufficiency may then result (p. 402); a small contracted kidney is found after death. It should be emphasized that (as first pointed out by Albutt) the hypertension *develops* in the absence of demonstrable kidney disease. The latter when it occurs is the result of the hypertension. In other words, kidney disease is not a forerunner of essential hypertension but a sequel to it.

PATHOGENESIS. The cause of the *increased peripheral resistance* is unknown, though many theories have been proposed.

The pressure is lowered temporarily by drugs which cause vasodilatation, such as histamine; in a number of hypertensive cases examined by Ellis and Weiss the arteriolar resistance was, as in

normal persons, removed by this drug. These facts indicate that the vasoconstriction is largely due to spasm (fig. 45).

(1) *Nervous influences.* It has been suggested that the essential cause of the increased peripheral resistance is an inherent hypersensitivity of the vasoconstrictor nerves and an exaggeration of the usual vasomotor responses. The demonstration of an hereditary susceptibility to hypertension which is said to be a *dominant* characteristic and transmitted according to Mendelian laws has been pointed to in support of the latter view. Also Lord Dawson in the examination of 650 school children found the blood pressure well above the

FIG. 45. Diagrammatic representation of fall in blood pressure in vascular circuit in subjects with hypertension compared with the normal. Shaded and stippled areas represent alteration in the pressure relationships in the skin vessels after the injection of histamine. The lower boundaries of these areas represent the pressure gradient under natural conditions; the upper boundaries this gradient after the injection of histamine (after Ellis and Weiss).

normal in 8 per cent. Hypertension has also been reported in infants.

In certain persons the response of the vasoconstrictor mechanisms to a cold stimulus—the so-called *cold pressor reaction*—is excessive. Hypertensive subjects commonly show a greater rise in blood pressure when a hand is immersed in ice water than do persons with a normal blood pressure (Hines). The cold pressor reaction also varies considerably among normal subjects. Those who respond to the cold test by a rise greater than 20 mm. Hg systolic and 15 mm. Hg diastolic are classed as hyper-reactors and are believed to possess a hypersensitive vasomotor system which renders them especially liable to

development of essential hypertension at some late date.

Though hypertension, temporary at least, may be produced in animals by denervation of the carotid sinuses (p. 244) and section of the aortic nerves there is no evidence that these mechanisms are directly concerned in the production of hypertension in man. The response of the carotid sinus to manual pressure (depressor response) is often actually more active in subjects of hypertension than in normal persons. Furthermore, in a study made by Thomas of the hypertensive effect of sectioning the sinus and aortic nerves in dogs, it was found that hypertension caused in this way differs from essential or renal hypertension in that increased cardiac output is an important factor in its production.

The nervous and emotional strain of modern civilization has frequently been pointed to as the underlying factor in the development of hypertension. There is little evidence which can be cited in support of the idea that mental strain, in the great majority of cases at any rate, is an important factor. In an analysis of some 30,000 applicants for life insurance Weiss found the average blood pressure no higher in medical men, teachers, lawyers, business men and others than in farmers who undoubtedly lead a life of greater mental calm. It should be mentioned, however, in this connection that Armstrong found in Air Force applicants a high correlation between hypertension and emotional instability, as determined by psychological examination. This finding applies, of course, only to healthy young men and not necessarily to women or to males of other ages.

(2) *Arteriosclerosis*. Ordinary senile arteriosclerosis which involves the larger and medium sized arteries does not cause hypertension. Some authorities have expressed the view that diffuse sclerotic changes in the systemic arterioles (p. 719) precedes the hypertensive state. On the other hand there is no doubt that such changes occur as a secondary effect of the strain upon the vascular tree induced by the heightened pressure. For this reason the question is a difficult one to answer definitely, yet obviously the finding of structural changes in the peripheral vessels cannot be taken as evidence that such changes are the primary cause of the hypertension and not secondary. It is conceivable, as Starling suggested, that obliterative vascular changes in the medulla would, by reducing the blood flow through the vasomotor center, (p. 292) cause hypertension. The possibility that

the latter is produced in this way in some instances cannot be ignored, but it is certainly true that such changes play no rôle in the great majority of cases.

The following experiments and observations indicate that excessive strain is a potent factor in the production of degenerative arterial changes. Josué and others have produced arteriosclerosis in rabbits by adrenaline injections. Sclerosis has also been induced in rabbits by placing them in the erect posture for a few minutes daily and so increasing the strain upon the arterial walls through the gravity effect. The sclerosis of the pulmonary artery which accompanies mitral stenosis is believed to be a result of the heightened pressure in the pulmonary circuit. Again, the removal of a section of artery and its replacement by a portion of vein is followed by sclerotic changes in the latter which are ascribed to the higher arterial pressure acting upon vascular tissue unsuited to withstand it; in aortic regurgitation the arteriosclerotic changes which occur are attributed to the constant buffetings to which the arterial walls are subjected by the high pulse pressure.

(3) *Toxic substances*. A great number of substances have been suggested as possible causes of the arteriolar changes responsible for hypertension. Among these are *cholesterol* which produces an elevation of the blood pressure in rabbits and arteriosclerotic changes. It has also been stated that subjects of hypertension have a high blood cholesterol. Critical investigations have failed to show, however, that this substance is causally related to hypertension. Pressor substances formed in the alimentary tract from the bacterial decomposition of protein, e.g. *tyramine* and *isocamylamine*, have also been suspected unjustly (see pp. 131 and 507). Lead, of all the toxic substances which have been suspected, appears to be the only one which in any way may be concerned with the development of hypertension. In lead poisoning the arterial pressure is elevated and degenerative changes are produced in the small vessels. Renal disease results.

(4) *The endocrines*. Excessive secretion of the *adrenal medulla* is not, except in those rare instances of adrenal adenoma (see p. 691), a factor in the production of hypertension. In *pituitary basophilism* (p. 737) (anterior lobe) hypertension does occur, through the hypertrophy or stimulation apparently of the adrenal medulla but there is no evidence that the anterior lobe or the hypertensive principle (pitressin) of the posterior lobe plays a rôle in ordinary essential hypertension. The same may be said of the *thyroid*. Though, as we have seen, hyperthyroidism may be accompanied by high blood pressure there is no evidence that the thyroid is concerned in the development of essential hypertension. If any substance, whether alimentary, metabolic or endocrine, in nature were responsible for the heightened blood pressure, one should expect that a pressor effect of the serum of subjects of hypertension could be demonstrated. Attempts to do so have failed.

Having in mind the experimental results of constriction of the renal artery in causing hypertension and the probability that renal ischemia is the cause of the high blood pressure in renal disease, the question immediately arises, "Is essential hypertension due to the same mechanism?" The hypertension in animals caused by a moderate degree of compression of the renal arteries (p. 129), with its relatively mild course and the absence of renal insufficiency, is comparable to "benign" hypertension in man; that caused by severe renal ischemia and accompanied by renal failure and widespread vascular damage resembles closely the malignant form of the human disease (see below). The observations of Moritz and Oldt may be cited in connection with the renal ischemia theory of essential hypertension. He has reported that in the histological examination of the kidneys of 100 hypertensive cases in which there had been no evidence of renal disease, arteriolar damage consisting of endothelial hyperplasia, medial hypertrophy and hyaline degeneration of the intima was an invariable finding. In the same number of kidneys from non-hypertensive cases, arteriolar disease was absent. So far as the systemic vessels were concerned, there was no corresponding distinction between hypertensives and non-hypertensives. These observations and those of others upon post-mortem material apparently indicated that either the walls of the kidney vessels are peculiarly susceptible to the hypertensive effect (i.e., that the renal vascular damage is secondary to the hypertension), which is unlikely, or that the arteriolar changes and the renal ischemia, consequent thereto, are the primary causes of high blood pressure. A more recent study by Castleman and Smithwick has failed, however, to support the renal ischemia theory of the origin of essential hypertension. The vascular changes in renal tissue removed at operation from hypertensive cases were not significantly greater than those found in the kidneys of persons with normal blood pressures.

Malignant hypertension

In this condition the hypertension is associated with wide spread degeneration and occlusion of the peripheral vessels. The media of the arterioles and small arteries show hypertrophy of their muscular tissue and fibrosis. Hyperplasia and degenerative changes are found in the intima. Small hemorrhages are commonly found in various regions due to the necrosis of the walls of the

vessels. As a result of the destruction of the glomeruli, renal failure ensues and death in uremia may occur. More usually death is by cerebral hemorrhage. This condition is probably of the same nature as the benign form but of a much more severe grade.

Eclampsia gravidarum

Eclampsia is accompanied usually by a very high blood pressure of rapid development. The diastolic pressure shows the more pronounced rise indicating a generalized vasoconstriction. The cause of the arteriolar spasm is unknown. The blood pressure, as a rule, falls after evacuation of the uterus, which fact together with other features of the eclamptic state suggests, that an abnormal metabolic product, or possibly an endocrine secretion, acting either upon the vasomotor center, or directly upon the vessels is responsible. Hyposecretion of the posterior lobe of the pituitary has been regarded as a possible cause. Anselmino and Hoffmann, for example, claim to have isolated a substance from the plasma of women in eclampsia which, when injected into rabbits, exerts an antidiuretic effect (p. 731), increases the concentration of urinary chlorides and raises the blood pressure. The convulsive seizures of the eclamptic state are attributed to the water retention (water intoxication, p. 19) consequent upon the antidiuretic effect of the hormone. This work has been confirmed. Theobald also obtained an antidiuretic principle from the blood of eclamptic cases but he denies its identity with that of the pituitary and Melville, who obtained a similar material from the blood in normal pregnancies, concludes that there is no causal relationship between the pituitary and eclampsia; other observers have come to the same conclusion. The possibility that the eclamptic state is due to a relative or functional ischemia of the kidney is suggested by the experiments already cited (p. 129). On the other hand, a pressor agent produced by chorionic tissue as a result of placental ischemia, may be responsible for the peripheral vasoconstriction and for the renal changes. Such a substance might act primarily upon the systemic and renal vessels causing hypertension, which in turn would lead to renal damage. Experiments have failed, however, to demonstrate a pressor substance in placental extracts either from normal or toxemic pregnancies.

HYPOTENSION

In an adult an arterial pressure which is persistently below 110 mm. Hg and for which no cause

be found is referred to as essential or primary hypotension. The subjects of essential hypotension, beyond showing possibly a greater susceptibility to fatigue, suffer no ill effects; on the contrary they are more likely to be free from cardiac and renal disease, the condition for this opinion being said to forecast longevity. Robinson says "Hypotension is not a disease; it is the ideal blood pressure level."

Apart from the foregoing type, low blood pressure occurs either as a temporary or a persistent phenomenon in many conditions. Some of these are hemorrhage, traumatic shock, anesthesia, tuberculosis and debilitating diseases of various kinds. It may occur also, as a result of the vasodilation and cardiac atrophy associated with acute fever; from myocardial failure; and in Addison's disease and in hypothyroidism.

Orthostatic hypotension is an unusual but interesting condition in which the reflex mechanisms normally operating to maintain the blood pressure against the effect of gravity are apparently in abeyance, or their sensitivity greatly depressed (p. 141). A profound fall in blood pressure occurs in the standing position; the systolic pressure may fall to 40 mm. Hg and the diastolic to zero (as determined by the usual method). The subject experiences dizziness or may fall in a faint. Other features of this condition are (a) absence of sweating, (b) failure of the pulse rate to increase upon rising from recumbency to the standing position, (c) slight depression of the basal metabolic rate, (d) loss of sexual desire, (e) skin pallor and (f) blood urea around the upper limit of normal. The inability to sweat, taken together with the failure of the reflex vasoconstriction to a change in posture, suggests some fundamental abnormality of the sympathetic nervous system. The administration of benzedrine sulphate effects some temporary relief by reducing the extent of the fall in blood pressure in the standing position.

VENOUS BLOOD FLOW

FACTORS WHICH INFLUENCE THE FLOW OF BLOOD IN THE VEINS

It has been mentioned (p. 117) that the blood pressure slopes gradually through the systemic capillaries and veins to the right auricle, but that with the narrowing of the venous bed from the "capillary lake" to the right side of the heart the velocity of flow increases. The following are the factors which influence the venous flow.

- (1) Contraction of the left ventricle.
- (2) The quantity of blood flowing through the arterioles from the arteries in relation to the capacity of the capillaries and veins.

(3) The subatmospheric pressure within the thorax.

(4) The action of the right side of the heart.

(5) The massaging effect of the skeletal muscles and the support afforded by the abdominal wall.

(6) The effect of gravity.

(1) *The contraction of the left ventricle* (the "vis a tergo"). The energy of the ventricular contraction as we have seen is expended in driving the blood through the arterioles and onward in the veins to the right auricle. By the time the blood reaches the auricle the energy has been almost entirely dissipated in overcoming the frictional resistance offered by the vascular channels; at this point the pressure is only about 5 mm. of water.

(2) *The quantity of blood flowing through the arterioles in relation to the capacity of the capillaries and veins.* Generally speaking, the more blood which is received from the arterial side the greater will be the capillary and venous pressures. That is, with dilated arterioles the difference between the arterial pressure on the one hand and capillary and venous pressures on the other, tends to be reduced; with constricted vessels the pressure difference will be increased. The relationship, however, does not always hold for the reason that the capillaries and veins are under nervous control (p. 250). As a consequence, the capacities of these vascular regions are capable of adjustment to the quantity of blood received from the arterial system. The capillaries and veins may dilate to accommodate the extra blood, so that little change in capillary or of venous pressure will result. Bayliss and Starling, for example, found that when the arterioles opened as a result of the stimulation of a vasodilator nerve (p. 233) the expected rise in venous pressure did not always occur, and Hooker observed that when the hands were warmed, more blood entered the veins but a rise in venous pressure did not result. On the other hand, if the arterioles constrict the capillaries and veins may, by an active contraction of their walls, reduce their capacities and thus maintain the pressure in spite of the reduced amount of blood which they receive.

(3) *Subatmospheric pressure within the thorax.* The intra-thoracic pressure has an important influence upon the flow of blood along the great veins of the thorax and abdomen and consequently upon the filling of the right auricle. During inspiration the pressure within the thorax is about -6 mm. of mercury (81 mm. H_2O) below that of the atmosphere. During expiration it amounts to about -2.5 mm. of mercury (34 mm. H_2O). The sub-

atmospheric pressure expands the thin-walled intra-thoracic veins and the venous blood is sucked into the thorax. A similar effect but of less degree is exerted upon the walls of the auricles, the diameters of the thick-walled ventricles, however, and the comparatively rigid coats of the larger arteries remain practically uninfluenced by the "negative pressure" during ordinary breathing. It has been mentioned that the blood in the great veins at their entrance into the auricle has a small but definite pressure of about 5 mm. H₂O transmitted from the arterial side. That is to say, if the thorax were opened so as to abolish the sub-atmospheric pressure within it and a manometer placed in the inferior vena cava a positive pressure of this magnitude would be registered.

The flow of blood toward the heart is thus furthered by both the positive pressure in the venous system and the suction pressure exerted by the thorax. The sum of these two is sometimes spoken of as the *effective venous pressure*. Thus, if the positive pressure in the great veins at the right auricle amounts to +5 mm. H₂O and the pressure within the thorax to -80 mm. then 85 mm. represents the effective venous pressure. Since the negative pressure in the thorax increases during inspiration, the effective venous pressure must likewise increase and auricular filling be hastened during this phase of respiration. The descent of the diaphragm during the inspiratory phase, also, by compressing the abdominal contents, increases the pressure in the inferior vena cava (the femoral veins and sometimes the iliacs being provided with valves) and augments the flow of blood toward the heart. The thorax thus acts as a pump which "lifts" the blood as well as "forces" it toward the heart (see fig. 131, p. 297). Sometimes when vigorous respiratory efforts are made, slight fluctuations of the venous pressure can be detected in the peripheral veins of the human subject. The variations rarely amount to more than 10 mm. of H₂O but may be considerably higher than this when dyspnea resulting from obstruction to the free entrance and egress of air from the lungs exists. Owing to the inertia of the blood column the aspirating effect is less evident the nearer to the periphery at which the pressure measurements are made.

The respiratory effects upon venous pressure can also be exaggerated in the normal subjects by the following procedures. If a forced expiration be made with the glottis closed (Valsalva's experiment) the negative intrathoracic pressure can be abolished and a positive pressure of several milli-

meters of mercury substituted. The veins of the neck, face and limbs become distended with blood as a result of the impediment to the flow into the right auricle. The peripheral venous pressure under these circumstances may rise to 400 mm. H₂O or more. In the converse experiment of Mueller in which a forced inspiration is made with the glottis closed, the powerful suction effect may cause a fall of 50 mm. H₂O or so in the venous pressure of a peripheral vein. The increase in negative intrathoracic pressure may be seen by means of the X-ray to exert an effect upon the ventricle which during diastole becomes somewhat enlarged beyond its usual size.

(4) *The action of the right side of the heart upon the blood-flow in the veins.* Obviously if the blood is not passed on again by the right heart as quickly as it is carried to it by the great veins, the velocity of the blood flow in the venous system will be reduced. As a result the venous pressure will rise. That is, there will be a tendency for the blood to be "dammed back." When the heart is beating vigorously and output and inflow are balanced no rise in venous pressure occurs. In health the force of the ventricular contraction is nicely adjusted (p. 215) to the quantity of blood which pours into the auricle from the veins and no accumulation occurs. If, however, the heart fails the venous pressure rises and back pressure effects ensue (p. 222).

The influence of cardiac action upon the movement of the blood in the veins must not be taken to imply that the heart exerts any aspirating effect. The ventricle does not "draw" blood from the auricle and great veins when it relaxes and expands as one would suck up fluid by means of a bulb-syringe. Such an action has been suggested but it is difficult to conceive how any significant effect of this nature could result even were a negative pressure appreciably below that within the thorax created within the heart chambers. The veins are thin walled and any reduction of pressure upon their outer surfaces, as we have seen, causes them to expand. But a lowering of pressure in their interiors would cause them to collapse, and the venous flow would be blocked automatically before the inertia of the blood had been overcome. Moreover, intra-ventricular pressure curves fail to show a negative pressure during cardiac relaxation (fig. 64) as might be expected if the ventricle exerted a suction effect upon the blood in the great veins.

It may be mentioned, however, that during *systole* the ventricle does cause a slight fall in pressure in the auricle and in the great veins due to the drawing down of the floor of the auricle (p. 170). Also as a result of the ejection of 60 cc. or so of blood from the thorax at

each beat a slight but sharp increase in the negative pressure within the thorax is induced during the cardiac contraction. This is reflected in the veins, auricles and other thin-walled intrathoracic structures. It may even be detected within the thoracic portion of the oesophagus by placing a balloon therein and recording the pressure change. These variations in intrathoracic pressure occurring during the contraction of the ventricle are known as the negative heart pulse or the cardio-pneumatic movements.

(5) *The massaging effect of the muscles.* The intermittent pressure which is brought to bear upon the blood by contraction of the limb muscles aids in propelling it towards the heart. The arrangement of the valves of the veins serves to give the blood flow this direction. The muscles thus act as subsidiary pumps which aid very materially the flow of venous blood, especially during muscular exercise, but to a lesser extent at all times, except when there is complete muscular relaxation. In strenuous exercise, on account of the much greater amount of blood entering the veins from the arterial side, there is a tendency for the venous pressure to rise; but this to a large extent is compensated for, provided the cardiac action is unimpaired, by the increased aspirating effect of the respiratory movements. The muscles of the abdominal wall also contract during exercise to lend support to the abdominal veins and prevent them from becoming over-distended. The venous reservoir is in this way not permitted to enlarge its capacity unduly for the accommodation of the increased volume of blood which, in consequence, is borne onwards to the right auricle.

(6) *The effect of gravity.* Besides the hydrodynamic factor, i.e., the energy of the cardiac contraction, in the development of pressure within the vascular system, there must also be considered the hydrostatic factor, or weight of the blood column, which comes into play when the erect posture is assumed. It is convenient to consider the arterial and venous systems together in their relation to the hydrostatic effect. Above the level of the heart gravity opposes the hydrodynamic factor in the arteries but aids it in the veins. Below heart level the reverse is true, the hydrostatic and hydrodynamic factors being summed in the arteries but opposed to one another in the veins.

In the case of the *arteries* the effect of gravity upon the blood in the vessels above heart level is fully compensated. That is, the pressure in the brachial artery is as high or actually higher when the subject is standing than when he is lying down. The pressures in the brachial and femoral arteries

are approximately equal in the latter position. Unlike the brachial pressure, the pressure in the arteries of the lower limb varies widely with the position of the body. When the subject is in the vertical head down position or in the L position (lying on back with lower limbs vertical) the pressure in the artery of the leg is much lower than it is in the recumbent position. In the standing position, on the other hand, the pressure in the leg artery is higher than in the lying down position (lower limbs horizontal); owing to the hydrostatic effect, the nearer the foot that the measurement is made the higher will be the observed pressure. The difference between the pressures in the brachial and the artery of the leg in these different positions is equal to the height of a blood column which would reach from one artery level to the other. In the case of the blood supply to the upper part of the body nervous mechanisms (p. 231) governing the caliber of the arterioles (especially of the splanchnic area) are called into play to antagonize the gravity effect. An adequate pressure in the cerebral vessels is thereby assured; but there is no corresponding mechanism for the maintenance of a constant blood pressure to the lower limbs, nor, in the natural positions of the body, is it required. The pressures in the brachial and posterior tibial arteries in different positions of the body are given in table 14.

Though the systolic pressures in the femoral and brachial arteries are usually about equal in the horizontal position, a marked difference between the two is seen in aortic regurgitation, the femoral systolic pressure averaging some 50 mm. Hg higher than the brachial pressure (L. Hill and Rowlands). A "differential" pressure of this character is also observed in exophthalmic goiter (average 37 mm. Hg higher in femoral) and in arteriosclerosis (average 8 mm. higher in femoral). It may also be seen in normal persons after muscular exercise. The differential pressure is attributed by Bazett to the greater resistance offered to the flow of blood in the femoral artery and the conversion, in consequence, of a greater proportion of kinetic energy into stress as the blood stream is slowed. The greater mass of the blood column entering the femoral artery as compared with that entering the brachial is also a factor.

It is through the *venous system* that the effects of gravity upon the circulation are the more prominently displayed. This is on account of the lower venous pressure, the greater distensibility of the venous walls, and also of the fact that the

height of the blood column which must be raised against gravity is much greater (from feet to heart) than that of the arterial blood column (from heart to brain). In man the mechanisms whereby the effects of gravity upon the venous system are offset are remarkably efficient. In monkeys also, the compensatory devices are well developed and in some varieties of these and in the anthropoid apes the effect of gravity is counteracted as effectively as in the human subject. In many of the lower animals, on the contrary, there is little evidence of compensatory mechanisms.

The factors which enable the blood in the veins below the thorax to overcome the gravity effect and to be carried to the level of the auricle are several. Let us consider for a moment a U-shaped tube with rigid walls. If liquid be permitted to flow into one limb of such a tube, the liquid, being

concerned with raising the blood against gravity may be given again here. They are:—

(a) The impetus given to the blood by the left ventricular contraction (*vis a tergo*).

(b) The abdominal and limb muscles support the vein walls and prevent their “giving” under the weight of blood. By this means the veins in a sense come to simulate rigid tubes. When the abdominal muscles are weakened or paralyzed the support which they normally provide is seriously impaired, but may to a large extent be restored by a tight abdominal bandage. The intermittent contraction of the skeletal muscles which in conjunction with the valves of the veins propel the blood in the upward direction. The important part played by the muscles in the return of blood to the heart is shown by experiments in which the body is passively tilted into the upright position.

TABLE 14
Showing effect of gravity upon the arterial blood pressure
(Modified from Hill and Flack)

POSTURE	BRACHIAL ARTERY PRESSURE	POSTERIOR TIBIAL PRESSURE	PRESSURE DIFFERENCES OBSERVED	PRESSURE DIFFERENCES CALCULATED FROM HEIGHTS OF BLOOD COLUMNS SEPARATING POINTS IN TWO ARTERIES
	mm. Hg	mm. Hg	mm. Hg	mm. Hg
Horizontal	106	106	0	0
Standing	110	165	55	58
Vertical, head down	115	50	65	65
L position, legs up	115	85	30	33

supported by the rigid walls, rises in the other limb until it overflows. After the liquid has been allowed to come to rest, then at any level of the tubing, the hydrostatic pressure corresponds to the height of the liquid column extending above that level. The aorta with the main arteries of the lower limb, and the inferior vena cava with its tributaries, are roughly comparable to two limbs of a U-tube. But the venous walls are highly distensible and quite incapable of supporting the blood column, and, unless the gravity effects were overcome, the blood would sink and “find its own level.” Furthermore, a system of small vessels—capillaries and venules—of variable capacity is interposed between the limbs of the U. In the corpse, for example, the blood subsides to the dependent parts, and the hydrostatic pressure when the body is held erect amounts to no more than a few centimeters of water.

Though the factors which aid the venous flow have already been dealt with, those especially

Persons who fail to show a rise in intramuscular pressure when tilted passively are likely to faint.

(c) The suction and force-pump action of the respiratory movements.

(d) The veno-pressor and capillary tonus mechanisms which, through the activity of the sinus and aortic nerves (p. 240), control the calibers of the small veno-capillary vessels of the splanchnic bed and prevent pooling of blood in this area.

If any or several of these factors fail, accumulation of blood (venous stasis) in the dependent parts of the body is likely to result. Thus, in the human subject if, upon assuming the erect posture after a protracted confinement to bed, the muscles of the abdomen and limbs are weak and the tone of the nervous mechanism governing the peripheral vessels lowered, the hydrostatic effect is overcome with difficulty. The blood subsides into the capacious abdominal veins and capillaries and the right heart is no longer adequately supplied with blood. The blood supply to the brain is reduced, with

diness (vertigo) or loss of consciousness (syncope) as a result. A sudden drop of about 25 mm. Hg is usually sufficient to cause unconsciousness. Even a healthy man may faint if kept standing and immovable in one position for a long period (e.g., a soldier standing to attention on parade). The blood is not driven upwards in the usual manner by the massaging effect of muscular movement. The failure of the right heart to receive an adequate blood supply to maintain the cerebral blood pressure affords a probable explanation of the syncope that occurs under these circumstances. It is an interesting reflection in this connection that when a person falls to the ground unconscious the horizontal position annuls automatically the effect of gravity. The head-low position and pressure upon the abdomen are obviously the most effective means of getting the blood to the heart and so restoring the circulation. On the other hand, if a person were held in the upright position after unconsciousness had been lost death might result, just as a domestic rabbit succumbs when held for a much shorter time in the head-up-feet-down position. Under chloroform and to a less extent under ether and other anesthetics, in shock and in various unconscious states the compensatory responses are depressed and any change from the horizontal position under these conditions is therefore fraught with serious danger to life. Certain vasodilator drugs and sodium nitrite (p. 254) annul the compensatory response, and it is relatively insensitive in severe arteriosclerosis (see also orthostatic hypotension, p. 136). That compensation is not perfect even in health is shown by the slight reduction in cardiac output (p. 226) which occurs in the standing position. Also, though an increase in blood volume results from a rise in environmental temperature, the compensatory vasoconstrictor response to a change from recumbency to the upright position is reduced by a rise in air temperature.

The effect of gravity upon the circulation in an animal such as the dog or cat which normally is fairly well able to compensate for postural changes, and the importance of the various factors comprising the control mechanism have been well shown by L. Hill. The medullary control over the peripheral vessels was removed by section of the cord at the level of the 1st thoracic vertebra. The tone of the abdominal muscles is also lost after this operation and the respirations are altered. The blood pressure falls even when the animal is in the horizontal position. When placed in the feet-down position, the pressure drops to zero. If the animal's abdomen be compressed the capacity of the

splanchnic vessels is thereby reduced and blood forced upwards to fill the right heart. The blood pressure is raised again and the circulation restored. In the head-down, feet-up position the rigid cranial wall supports the blood column, the heart fills and the carotid pressure rises. When the main nerve trunks (splanchnics, p. 940) carrying fibers to the peripheral vessels are divided alone the respiratory pump in part compensates for the gravity effect, and though marked changes in pressure occur when different positions are assumed the circulation is maintained. Edholm found that the blood pressure of normal cats under chloralose anesthesia fell by 34 mm. Hg on the average when the

FIG. 46. Apparatus for the determination of venous blood pressure in man by the indirect method. For detailed description of parts see "Clinical measurement of venous pressure." Eyster. Macmillan. 1929.

animal was held in the vertical feet-down position, but recovered shortly to a final pressure within 30 mm. Hg of its previous level in the horizontal position. It appears from Edholm's results that pooling of blood under the effect of gravity occurs in the liver and not to any great extent in the splanchnic vessels generally, for the fall in blood pressure in the feet-down position was about the same after evisceration as before, whereas, after removal of the liver from eviscerated animals, the vertical feet-down position caused a fall in blood pressure of only from 5 to 10 mm. Hg. That the splanchnic vascular bed is, nevertheless, a factor in the compensatory mechanism tending to oppose the effect of gravity was indicated by the observation that the

final height of the blood pressure in the foot-down position was higher in normal than in eviscerated animals.

The circulation of animals such as the domestic rabbit or the snake, which have not acquired a compensatory mechanism, is placed at a great disadvantage when the vertical position is assumed.¹ This has been shown very clearly upon the latter species in the following experiment. The heart and abdominal vessels were exposed and the reptile fastened to a board. The right side of the heart was seen to be adequately supplied with blood so long as it was held in the horizontal position. When placed vertically the auricle was no longer properly filled and the great veins entering the heart were nearly empty. When the preparation was then immersed in a cylinder of water up to the heart level the hydrostatic pressure of the venous blood was counterbalanced by that of the surrounding water, and the blood again flowed freely into the heart chambers.

THE CLINICAL MEASUREMENT OF THE VENOUS PRESSURE

Hooker and Eyster have devised an instrument for the *indirect measurement* of the venous pressure based upon the principle first employed by von Recklinghausen.

In its present improved form the instrument consists of a small round chamber with a glass top and metal walls (fig. 46). Over the bottom of the chamber is stretched a piece of rubber dam with an opening about half an inch square in its center. Lengths of rubber tubing connect the cavity of the chamber, respectively, with a water manometer and a small hand bulb. The rubber dam is moistened with glycerine and placed with its central opening lying over the vein to be examined. The pressure within the chamber is raised by a few compressions of the bulb. The venous pressure will equal that required to cause collapse of the vein. This pressure is read from the manometer at the instant that collapse occurs. All determinations are made with the vein at the level of the auricle so as to annul the hydrostatic effect. The part is supported in order to ensure complete muscular relaxation and the subject should be at rest for 15 minutes prior to the determination. If the pressure is measured with the subject recumbent, the vein, e.g., median basilic or a vein of the forearm or hand, is placed at a point situated one-third of the distance from the sternum to the back at a level of the 4th intercostal space. If the measurement is made in the sitting position the vein is brought to the level of the 4th interspace.

The venous pressure may also be determined *directly* though less conveniently and with more discomfort to the subject but no more accurately by the insertion into the vein of a hollow wide-bore needle, as first employed by Moritz and von Tabora.

¹ Sheep sometimes collapse and die when held upright during bleeding.

A simple indirect method which gives approximate results is that of Gaertner. With the patient in the supine position the hand is first lowered below heart level until the veins on the back of the hand fill. The part is then slowly raised until the veins collapse. The distance of the vein in millimeters above the auricle at which collapse occurs gives the venous pressure in millimeters of blood. The vein represents a manometer tube connected with the auricle and the level at which the vein empties indicates the point where the venous pressure at the auricle just about equals the weight of the blood column.

NORMAL VENOUS PRESSURES

The pressure in the median basilic vein taken with the body recumbent shows considerable variations in different individuals. The range is between 40 and 110 mm. H₂O. The pressure is greater in veins nearer the periphery and shows a progressive diminution toward the heart. It must be remembered that the pressure as measured is the algebraic sum of the positive pressure transmitted from the arterial side and the negative pressure exerted upon the blood column from the thoracic cavity. The effect of the latter is slight in the peripheral veins, but as the thorax is approached the venous blood comes decidedly under its influence. According to Burton-Ogata the decline in pressure along the peripheral veins amounts to 1 mm. Hg (13.5 mm. H₂O) for each 35 mm. distance. The point of zero pressure i.e., where negative and positive pressures just balance one another, is in the case of the upper part of the body, in the jugular vein at the root of the neck below this point the pressure is negative.² As

² For this reason there is supposed to be danger should a vein be nicked in this region during an operation, air being sucked in, and carried to the heart. The air might then be shipped up with the blood and cause frothing within the cardiac chambers, with resulting acute cardiac failure or pulmonary embolism, or even reach the arterial system and cause blockage of a cerebral vessel. The fear of air entering the vein under such circumstances, however, would appear to be exaggerated. The walls of the vein collapse under the suction pressure within and appose one another close the lumen. Furthermore, even should a small amount of air enter the vein, it is unlikely that serious effects would ensue, since to produce the effects just described in an animal relatively large quantities of air must be injected. Dukes, Richardson and Hall have observed from their experiments upon dogs that about 500 cc. of air in the circulation would be lethal for a human being. A more likely portal for the entrance of air into the circulation is via the uterine veins during the induction of abortion or blowing labor at term. Several fatalities supposedly due to this cause have been reported. It may also occur during the collection of air into the pleural cavity for the production of pneumothorax. It is probable, however, that in many instances in which death has been attributed to air embolism it has been due to some other cause.

ed above, it varies between -35 and 0 mm. H_2O at the right auricle.

Point of zero venous pressure below the heart at about the level of the entrance of the veins into the vena cava (Barton-Ostiz). Venous pressure varies, of course, as a result of gravity effect, with the position of the vein in relation to the auricle. In the veins of the hand, for example, the pressure is lower by from 50 to 100 mm. H_2O when the hand is at heart level than it is dependent. The differences in pressure arising from changes in the vein's level will obviously be larger in the case of the lower limbs. Since certain factors, already mentioned, enter into the gravity effect the actual differences as observed do not coincide with the height column of blood from the vein level to the heart.

The greater the velocity with which the blood flows upwards the greater will be the discrepancy between the calculated pressure and that actually measured (see also p. 114). For example, the hydrostatic pressure of a column of blood extending from the foot to the heart would amount to over 1200 mm. H_2O . The pressure as actually measured in the vein of the foot in the standing position is only a fraction of this. The effect of muscular exercise upon the venous pressure has been considered (p. 139). The relation of venous pressure to heart rate and cardiac output is discussed with on pages 209, 216, 224 and 227.

VARIATIONS IN VENOUS PRESSURE

Muscular Exercise causes a prompt rise in the pressure of blood in the veins of the exercised parts. **Constriction of a peripheral vein** will, of course, cause a local rise in venous pressure and compression of the large intrathoracic veins will be followed by a general rise.

Cardiac failure. As the right ventricle weakens and dilates, the pressure in the right auricle rises and is transmitted to the blood in the portal and systemic veins (see fig. 47). The pressure in the median basilic vein may reach a value of over 100 mm. H_2O . The increased pressure distends the veins and capillaries of the portal system; the liver becomes enlarged and the other abdominal organs engorged. The rise of pressure in the systemic veins and capillaries increases the filtration pressure, edema results. The slowing of the flow through the small vessels of the skin causes cyanosis. Both edema and cyanosis tend to be more pronounced in the dependent parts (feet and ankles). The rise in pressure in the veins results in slowing of the circulation

through the glomeruli, the urinary secretion is reduced. The rise in pressure in the cerebral veins leads to slowing of the intracranial circulation, especially when the patient is recumbent and the venous return from the head is, therefore, not aided by gravity. Failure of the left side of the heart causes a rise in pressure in the left auricle which is transmitted to the pulmonary circuit and ultimately to the right side (see also p. 222). The lung vessels distend and encroach upon the air spaces. With the improvement in cardiac

FIG. 47. Upper drawing, normal subject supine with head on pillows. The zero level (Z.L.), indicated by the top point of swelling of the external jugular vein, lies a little below the manubrial line (M.L.). Lower drawing, illustrating excessive venous pressure equivalent to about 8 cm. of water. In the upright position the zero level may be just a little above the clavicle, as the subject is inclined the zero level comes to occupy a higher and higher position in the neck until it reaches to the angle of the jaw. Its vertical distance above the manubrium alters very little, however, with changes in position (after Lewis).

action induced by rest and digitalis administration, the venous pressure falls.

In hypertension, except when myocardial failure is impending or has supervened, the venous pressure is within normal limits.

In the stage of excitement during the induction of anæsthesia a very considerable elevation of the venous pressure may occur. The effects of disturbances of the respiratory mechanism upon venous pressure are also seen in convulsive attacks (p. 368) and in Cheyne-Stokes breathing (p. 352). The pressure rises to 180 mm. H_2O or so during

the phases of apnea of the latter condition, but approaches the normal value during the periods of hyperpnea. Reduction in the carbon dioxide content of the blood, if extreme, lowers venous pressure by increasing the tone of the peripheral vessels.

In severe *hemorrhage* and *surgical shock* the venous pressure is subnormal.

THE EFFECTS OF ACCELERATION UPON THE CIRCULATION

A constant speed, however great, has in itself no effect upon the circulation. As pointed out by Armstrong, we are travelling through space quite unaware of a speed of over 18 miles per second caused by the motion of the earth. But acceleration, that is, a change in velocity either in the line of our motion (linear acceleration) or a change in direction, as when a body travelling along a straight course turns into a curvilinear one (centrifugal acceleration), may cause profound effects upon the body as a result of the inertia of the blood and viscera. The development of the modern airplane and the manoeuvres of military flying have brought prominently to the fore in recent years the importance and hazards of acceleration in relation to the circulation. According to Newton's Law, $F = MA$ where F = force, M the mass and A the linear acceleration. Therefore, $A = \frac{F}{M}$. That is

linear acceleration is proportional to force and inversely proportional to mass. Centrifugal acceleration depends upon the *rate* of change in direction and upon the velocity. It is expressed

by the formula $F = \frac{MV^2}{r}$ in which V is the velocity

and r the radius of rotation. Now, weight is a measure of the force of gravity and is proportional to mass. The force of gravity is used, therefore, as the unit of measurement of acceleration and is

denoted by the letter "G". Thus, an acceleration of 2 Gs indicates a force double that of gravity. Acceleration which produces a force acting upon the airman in the long axis of the body from head to seat is called positive (+G); that acting from seat to head is called negative (-G). A pilot pulling out of a power dive, that is, changing direction at high velocity to a horizontal and upward direction has his head directed inward toward the center of rotation and is therefore subjected to a positive centrifugal acceleration. If the force amounts to from 5 to 6+ G, or more, the phenomenon now generally referred to as "blackout" results, for the blood, owing to its inertia is "forced" into the lower part of the body (the large vessels, it will be recalled, run in the general direction of the long axis of the body). The venous return to the heart is reduced and, as a consequence, the pressure of blood in the cerebral and retinal vessels falls. Vision is temporarily lost and the pilot may become unconscious. The abdominal viscera are forced downwards and drawing upon the diaphragm may embarrass respiration.

Negative acceleration, as when a turn is made at high velocity in pulling up from horizontal flight, the pilot's head being directed outwards, causes opposite effects upon the circulation. Blood is forced toward the head. The vessels of the head and neck become engorged, there may be small cutaneous hemorrhages, severe throbbing pain in the head is experienced and the eyes feel as though they were being extruded from their sockets. The abdominal viscera are pushed upwards against the diaphragm. The venous return to the heart is increased and the blood pressure in the cerebral vessels is raised considerably (as much as 65 mm. Hg). There may be mental confusion for a time. Cerebral hemorrhage may result.

CHAPTER XVII

THE VELOCITY OF THE BLOOD

The relative blood velocities in different parts of the circulation are dependent upon the sectional areas of the respective vascular beds (see p. 119). The velocity of the blood through the circulation as a whole, on the other hand, varies in accordance with the quantity of blood ejected per unit of time from the heart.

The velocity of the blood may be considered from four different aspects which are indicated by the following terms:

- (a) The mean lineal velocity.
- (b) The circulation time.
- (c) The volume flow.
- (d) The circulation rate or output of the heart.

The output of the heart (d) will be dealt with later (Chapter XXVI). The other three measurements will be considered now.

(1) THE MEAN LINEAL VELOCITY

By this term is meant the distance which the column of blood travels in a measured period of time along a given vessel, e.g., the carotid, femoral, etc. In very small transparent vessels, for instance those of the mesentery of a mammal or those in the tongue or toe-web of a frog, the blood velocity can be measured by timing the progress of a red cell beneath the microscope. In the large vessels the velocity can be calculated if the quantity of blood which passes a given point in a unit of time and the cross area of the vessel are known. It is, of course, not permissible merely to sever an artery and measure the amount of blood which escapes over a certain period, since such a procedure would completely alter two of the most important factors in the circulation, namely, the total blood volume and the peripheral resistance. Several instruments have been devised for measuring the volume of the blood flow in animals while the normal circulation is maintained.

Of such instruments the *Stromuhr* of Ludwig is one of the oldest and the best known (fig. 48). It consists of an ingoing and an outgoing cannula which are inserted, respectively, into the proximal and distal sections of a divided artery. The blood flowing from the artery into the instrument enters a small pear-shaped flask of known capacity filled with oil. Upon the entrance of the blood the oil is forced over into another flask of identical size but which has previously

been filled with saline. The entrance of the oil forces the saline in turn into the peripheral section of the artery. When flask 1 is filled with blood and flask 2 with the transferred oil, the instrument is rotated through a semicircle. This reverses the positions of the flasks and the process of filling and emptying is repeated. The blood in flask 1 is now forced into the peripheral part of the artery as blood enters flask 2 and displaces the oil as before. From the number of fillings of the flasks during the period of observation the volume of blood flowing in a unit of time is readily calculated. This value divided by the cross area of the vessel, since velocity is inversely proportional to the sectional area, gives the lineal velocity. Thus $V =$

$\frac{v}{\pi r^2}$ where V = velocity in millimeters per second, v the volume of blood in cubic millimeters flowing into the instrument in a given time and r the radius of the artery in millimeters. For instance, if the flow is 3000 c.mm. per second and the diameter of the vessel is 4 mm., the cross area is $\pi \left(\frac{4}{2}\right)^2 = 3.14 \times 4 = 12.56$ sq.mm. and the velocity is $\frac{3000}{12.56} = 238$ mm. per second.

This determination, of course, ignores the fluctuations in velocity which occur during the cardiac cycle,¹ and in consequence gives only the average or mean velocity. It may also be recalled that the velocity is not the same at different points along the radius of the blood column, the flow being much greater in the axial part of the stream than toward the circumference.

THE *thermo-stromuhr* OF REIN. In this method the blood as it flows past a point in the vessel (which is exposed but not opened) is heated by means of electrodes connected to a high frequency current. The temperature of the blood is measured below and above the heated region by means of thermojunctions. The magnitude of the temperature difference is a function of the blood flow and is used as the basis for the calculation of the latter. The temperature difference diminishes with increased blood flow and vice versa. This method is accurate and possesses the advantage that it entails little or no disturbance of the circulation (fig. 49).

¹ The velocity rises during systole and falls during diastole. There is therefore a pulse of velocity as well as of pressure. Green and his associates found that the velocity of blood flow in the aorta of the dog rises abruptly during systole, its maximum coinciding with the peak of the pressure curve, and then declines, gradually at first and later suddenly. It reaches zero at the commencement of the protodiastolic period (p. 173). Back flow occurs during the latter period. After this, forward flow is resumed and reaches a second maximum but not as great as the first, in the middle of diastole. Velocity of flow then declines gradually to the end of diastole.

The velocity in the larger arteries of the dog during rest is from 0.1 to 0.2 meter per second, in the capillaries about 0.5 mm. per second and in the medium sized and large veins from 0.06 to 0.2 meter per second.

FIG. 48. Ludwig's stromuhr. 1 and 2, glass flasks; *d*, metal turn-table; *a*, *a*, section of artery. Arrows indicate direction of blood flow.

FIG. 49. Thermo-stromuhr. *A* shows its application on a blood vessel; *B* shows a cross section of the blood vessel as it lies between the electrodes (platinum plates) *d* and *d'*, and on a thermojunction *x*. *C* shows the relative positions of plates and thermojunctions. *x* and *x'* are connected to a Zeiss loop galvanometer by leads 1 and 4. *d* and *d'* are connected to leads 2 and 3 (after Herrick, Essex and Baldes).

There is no reliable method for determining the mean lineal velocity of the blood in man. Attempts are sometimes made to arrive indirectly at a rough approximation by the use of certain data obtained in other ways, e.g., output of the heart (p. 228) and the cross section of the aorta in the

cadaver (p. 117). The velocity in the latter vessel is probably around 0.4 meter per second during bodily rest. Estimations of the flow in the arteries of the arm may be made from determinations of the volume flow through the hand by the methods described below, and the diameter of the brachial.

(2) CIRCULATION TIME

By this is meant the time which a particle of blood takes to make the complete round of both the systemic and pulmonary systems—*total circulation time*—or of the pulmonary circuit alone—the *pulmonary circulation time*. That is, if the voyage of a red cell could be timed from the moment it passed a given point, say in one jugular vein, to the moment when it arrived at the point from which it started or at a corresponding point in the opposite jugular the time consumed would be the total circulation time. The red cell must have traversed in succession the jugular vein, the right heart chambers, the pulmonary vessels, the left heart chambers, the arteries and then the veins of the head and neck. The time taken in passing from the jugular to the carotid is the pulmonary circulation time.

Measurement of the circulation time. This has been accomplished in animals in various ways, e.g., by the injection of potassium ferrocyanide into the vein and having the blood from the other vein or artery fall upon a revolving drum covered with paper soaked in ferric chloride solution. The appearance of the Prussian blue reaction indicates the completion of the particular circuit which is being timed. Methylene blue may be injected and the time noted when discoloration of the opposite vessel occurs. Stewart who employed the latter method also devised an *electrical method* in which a 2 per cent solution of sodium chloride is run into the vein. Two platinum electrodes separated from one another by a short distance are laid in contact with a vessel (jugular or carotid) of the opposite side. The electrodes are connected up as a resistance in one arm of a Wheatstone bridge. This is balanced with the resistance in the other arm. As the salt solution of high electrical conductivity reaches the section of vessel beneath the electrodes the electrical balance is upset by the sudden fall in resistance which results. This is recorded by the swing of a galvanometer or the ringing of a bell.

In man the circulation times have been measured by the injection of the dye fluorescein into the arm vein of one side and timing its arrival at a corresponding vein of the opposite arm; by the intravenous injection of histamine (0.001 mgm. histamine phosphate per kilogram of body weight)

and noting the time at which the flushing of the face, due to capillary dilatation, occurs; or by injecting glucide or decholin and having the subject signal the instant that he experiences the sweet or bitter taste, respectively. In the first mentioned method the dye traverses the arm vein, the right heart chambers, the pulmonary circuit, left heart, arteries of the opposite arm, capillary bed and finally the arm vein of the opposite arm. Its arrival at a point in the latter vessel is detected by drawing off samples of blood at 5-second intervals.

Blumgart and Yens have devised a method in which an active deposit of radium is injected into the antecubital vein of one side and its arrival detected by means of an instrument sensitive to radioactivity, at the right auricle and at the antecubital *artery* of the opposite side. The detecting instrument must, of course, be shielded by means of lead sheets from the action of the radioactive substance except at these two points. The arm to arm time, less the arm to heart time, is taken as the "crude pulmonary circulation time." Since the time consumed in traversing the aorta, subclavian artery and the artery of the opposite arm is very brief (a second or less) the measurement obtained in this way must approximate very closely the true pulmonary circulation time. A more convenient method for determining the pulmonary circulation time has recently been devised by Robb and Weiss based upon the fact that cyanide stimulates the respirations through its action upon the carotid sinus; 0.11 mg. of sodium cyanide per kilogram of body weight is injected into the arm vein and the time recorded by means of a pneumograph and stop watch.

NORMAL VALUES. 1. *Total circulation time.* Between veins of the two arms (fluorescein method) average 21 seconds (12 to 26 seconds). Arm to face (histamine method), average 24 seconds.

2. *Arm vein to corresponding artery of the opposite side* (radio-active method), average 18 seconds (14 to 24 seconds).

3. *Arm to heart* (radio-active method), average 6.6 seconds (2 to 14 seconds).

4. *Pulmonary circulation time* (radio-active method), average 11 seconds (5 to 17 seconds).

The circulation time is a measure of the *shortest* time which any particle of blood takes in passing from one point in the circulation to another. It is evident that if all the blood channels between the two points are not approximately uniform in length and diameter only a part of the blood will travel from point to point at the rate indicated by the measurement. It is believed, however, that the flow of blood through the lungs occurs

at an approximately uniform rate in different vessels and that the pulmonary circulation time may be taken as an index of the mean velocity of the pulmonary blood flow. It therefore bears a relation to the total volume of blood traversing the lungs in a given time, i.e., to the output of the heart (p. 225), being short with large outputs and long when the output is small.

Knowing the pulmonary circulation time and the output of the heart per minute the volume of blood contained in the lungs may be calculated from the following equation—

$$V = Q \frac{60}{T}$$

where V = the cardiac output, Q , the quantity of blood in the lungs and T the pulmonary circulation time. Q averages about 8 per cent of the total blood volume.

A close relationship exists between the size of the animal and the circulation times, these being shorter in a small than in a large animal. This is to be expected since the distances are shorter. The pulse rate also bears a relation to the animal's size, the smaller the animal the higher the rate. As a consequence, the product of the pulse rate and the pulmonary circulation time is almost the same in different species.

The circulation times are markedly reduced (velocity of blood increased) during muscular exercise or by the injection of adrenaline. They are altered in the following pathological conditions.

A. CONDITIONS ASSOCIATED WITH A REDUCED CIRCULATION TIME:

Hyperthyroidism. The decrease is closely related to the height of the metabolic rate.

Anemia (see p. 358) the increase in blood velocity is in proportion to the reduction in oxygen-carrying capacity of the blood.

B. CONDITIONS ASSOCIATED WITH A LENGTHENED CIRCULATION TIME:

Hypertension, normal or slightly lengthened.

Myxedema.

Polycythemia vera.

Cardiac failure. The engorgement of the systemic and pulmonary vessels results in a great increase in the quantity of blood contained in the lung and peripheral vessels. The speed of the blood through these vascular areas is reduced though the total volume of blood flowing through the distended vessels in a unit of time is not necessarily diminished (see below). The improvement in cardiac action following the administration of digitalis is accompanied by shortening of the circulation time. This drug causes no effect upon blood velocity in normal persons.

Postoperative. Smith and Allen found that

starting about the 5th day after operation the foot to carotid circulation time increased gradually to the 10th day when it was 50 per cent greater than the preoperative value. These observations are pertinent to the question of postoperative thrombosis (see p. 96).

(3) THE VOLUME OF BLOOD FLOWING THROUGH AN ORGAN OR CIRCUMSCRIBED REGION OF THE BODY; THE MASS MOVEMENT OF THE BLOOD

The total volume of blood flowing through an organ in a given time should not be confused with the velocity of the blood stream in the individual vessels, i.e., the speed of the blood corpuscles which, as mentioned above, is referred to as the lineal velocity. The two do not alter to the same degree, or necessarily, indeed in the same direction. If the pressure head remains unchanged then the

If the capillaries do not alter in caliber, or do so to a minor extent when the arterioles dilate, the velocity of the blood flowing through the capillaries is also increased. If, on the other hand, the total cross area of the vascular bed of the organ is enlarged as a result of capillary dilatation an opposite effect upon the lineal velocity of the blood in these vessels is produced which tends to counteract the effect upon velocity caused by the arteriolar dilatation (velocity being inversely proportional to the cross area of the vascular bed, p. 114). It thus comes about that with a constant arterial pressure the speed of the blood in the capillaries of a part may be reduced though the total volume of blood passing through it remains unaltered or is even increased. In the case of the lungs, for example, whose vessels of course offer the only route for the blood from the right to the left side of the heart,

FIG. 50. Diagram showing Hewlett and Van Zwaluwenburg's method for estimating the rate of blood flow in the arm (after Hewlett and Van Zwaluwenburg).

volume of liquid flowing in a unit of time along a narrow tube comparable in size to the small and medium sized arteries is proportional to the fourth power of the diameter of the tube. The lineal velocity, on the other hand, is proportional only to the sectional area of the tube (p. 114). When the arterioles of an organ dilate, though the peripheral resistance is reduced locally, compensatory vasoconstriction in other vascular areas occurs (Lovén reflex, p. 246) and a fall in general blood pressure does not ordinarily result. That is, the pressure head in the vessels feeding the organ remains at, or may even rise above, its original level. A greater volume of blood therefore flows through the organ and the velocity of the blood in its larger vessels increases. The capillary blood pressure increases for, as a result of dilatation of the arterioles, less energy is expended in overcoming the frictional resistance in these vessels

dilatation or constriction of the arterioles and capillaries unaccompanied by any change in the output of the right ventricle will not alter the volume of the pulmonary blood flow. The velocity of the blood through the small vessels will, however, be reduced or increased respectively with the expansion or constriction of the pulmonary vascular bed. Conversely, owing to the occurrence of compensatory changes in the capacity of the vascular bed, a reduction or increase in the cardiac output (and so of the quantity of blood passing through the lungs or through the peripheral parts of the body) does not necessarily alter the velocity of the blood through the individual vessels of the pulmonary or systemic circuits.

Approximate values for the volume flow per 100 grams of tissue per minute for various organs of animals are given below:

Thyroid.....	560 cc.	
Kidney.....	150 cc.	
Liver.....	150 cc.	{ arterial, 35 cc. portal, 115 cc.
Brain.....	136 cc.	
Intestines.....	70 cc.	
Spleen.....	40 cc.	
Stomach.....	25 cc.	

In *animals* one of three methods may be employed for the measurement of the volume flow through an organ.

(1) The simplest method is to collect and measure the blood issuing from the vein or veins of the part. This method can be employed only over relatively short periods and with small well circumscribed organs such as the kidney or salivary gland.

(2) If there is a single artery or vein supplying or draining the organ the stromuhr may be inserted into either vessel and the quantity of blood measured which enters or leaves the region, or the thermostromuhr method may be employed (p. 145).

(3) *The plethysmographic method of Brodie.* This is based upon the principle that if the venous return be occluded any change in volume of the part which results during the period of occlusion must represent the amount of blood which has entered the part during that period. The time during which the vein is compressed and consequently the duration of the observation must obviously be brief, for interference with the venous flow will automatically slow the blood stream and give a fallacious result. The organ, e.g., the kidney, with its blood vessels intact, is placed in an air-tight chamber (plethysmograph, p. 251). At the point where the vessels enter and leave the chamber a non-resistant material, e.g., sponge or tow packing smeared with vaseline, is used to form a hermetic seal so that compression of the vessels is prevented. A tube leads from the interior of the chamber to a tambour and recording apparatus. The excursions of the latter are calibrated to represent cubic centimeters of blood. To estimate the blood flow the vein is suddenly clamped and the increase in volume of the organ recorded over a short period. The method has been claimed by Brodie to give results comparable in accuracy with those obtained by means of the stromuhr. Brodie's method

has been adapted by Hewlett and Van Zwaluwenburg to the estimation of the volume flow in the human hand and forearm. A narrow cuff encircling the upper arm is employed to compress the veins (fig. 50).

The calorimetric method. This was devised by G. N. Stewart for the measurement of the volume flow through the human hand. Briefly, the method is based upon two assumptions (1) that the hand is a perfect radiator, and when immersed in a small body of water the blood coursing through its vessels gives up heat, so that its temperature comes to equal the average temperature of the surrounding water during the course of the observation,² (2) that the blood is the only source of heat, the heat generated by the muscular tissue of the hand being negligible.

The amount of heat (gram calories) given out by the hand to the water is obtained by multiplying the quantity of water in grams by the number of degrees centigrade through which its temperature has been raised. The blood flow in grams during the whole period of the observations is obtained from the following formula—

$$Q = \frac{H}{T - T^1} \times \frac{1}{S}$$

where Q equals the quantity of blood (grams), H the heat (gram calories) given out to the water, T and T¹ the temperatures of the arterial and venous bloods respectively and S the specific heat of blood (0.8). The difference between T and T¹ represents the drop in temperature of blood in passing from the arterial to the venous side.

A pair of specially designed water calorimeters of about 3000 cc. capacity are employed for the observations.

The blood flow through the hand is thought to be indicative in a general way of the flow through the peripheral parts of the body. The normal flow at ordinary room temperature 65°F. has an average of about 13 grams per minute per 100 grams of hand substance. A rise in the environmental temperature causes a marked rise, a fall in temperature curtails the flow.

² That the temperature of the venous blood may be taken as that of the average temperature of the water in the calorimeter has been questioned by Sheard.

CHAPTER XVIII

THE ARTERIAL PULSE

THE NATURE OF THE PULSE WAVE

The pulse is the pressure change created by the ejection of blood from the heart into the already full aorta and propagated as a wave through the blood column and arterial wall to the periphery. If the walls of the system were absolutely rigid, since liquids are incompressible, an impact delivered at one end would cause a pressure change to be transmitted instantaneously as through a steel rod to the furthestmost parts. In the case of elastic tubing, such as composes the vascular system, the pressure change is accompanied by an expansion of the tube's wall. It should be emphasized that the extra blood which is thrown into the aorta and the pulse wave which is the direct result of the former, do not pass along the vessel in company. If the ejected blood were made distinguishable in some way and its speed compared with that of the pulse wave it would be found that the latter travelled at a rate from 10 to 15 times faster than the former. The speed of the blood depends upon factors which have been considered elsewhere, e.g., pressure gradient, cross-sectional area of the vascular bed, etc., while the velocity of the pulse wave is determined almost entirely by the resilience of the arterial wall.

The independence of the velocity of a liquid and of a wave in that liquid will be evident if one considers what occurs when, say, a bucket of water is thrown into a running stream. Waves are then set up which travel through the water at a rate which has no relation to the velocity of the stream itself. They run up the stream against the current as well as down. Though the pulse wave in its passage gives some forward movement to the blood, i.e., increases its velocity at the moment of its passage just as a wave upon a river slightly speeds the flow of water, as is shown by the impetus which it gives to a floating cork, yet the chief phenomenon is a propagation of a change of form and pressure. It is a molecular movement rather than a translation of fluid en masse. The particles of the fluid change their positions relative to one another, but to a comparatively small extent in relation to the arterial wall—a pulse wave travels through a perfectly stagnant blood column, as in a ligated vessel. This distinction may be illustrated by the diagram in figure 51.

Measurement of the speed and length of the pulse wave

The velocity of the pulse wave in the brachial artery is normally from 5 to 8 meters per second. By means

of a pair of tambours, writing levers and a time marker (p. 189) the difference in the times of arrival of the pulse wave at a near and at a far point of the vascular system can be determined. The time difference divided into the distance travelled between the two points gives the velocity of propagation of the wave. Thus—

$$\frac{\text{Distance in mm.}}{\text{Time in seconds}} = \text{velocity in mm. per second}$$

Since the rate of propagation of the pulse alters with the state of the arterial wall, increased rigidity causing more rapid transmission and vice versa, the velocity is increased in old age or when the elasticity of the vessels is reduced by disease, e.g., arteriosclerosis. Bramwell, Hill and McSwiney found a speed of 5.2 meters per second at the age of 5, and one of 8.6 meters per second at 84 years. Also in hypertension (pathological or resulting from muscular exercise) the walls of the vessels are more strongly stretched and thus are nearer their elastic limit; the pulse wave is therefore transmitted at a higher speed. Vaso-dilatation or low pressure from any cause, on the other hand, reduces the velocity of the pulse wave. The femoral artery is less distensible than the brachial and the velocity of the pulse is greater in the former vessel.

The length of the pulse wave. The length of a pulse wave tracing gives no indication of the length of the pulse wave itself. The tracing is inscribed by the rise and fall of the lever as the wave passes the point in the artery (fig. 52) and its length depends upon the rate at which the writing surface moves. When the rate is fast the curve is lengthened and vice versa. The pulse wave itself is in reality a very long swell or billow. The ejection of blood from the ventricle does not cause simply a small local dilatation but an extensive expansion of the arterial channels.¹ The wave measures from 3.50 to 5 meters and consequently the greater part has disappeared from the periphery before its end has left the aorta. The length of the wave may be determined from the following formula. $L = VT$, where L equals length of wave, V the velocity of transmission and T

¹ It is also to be remembered that the amplitude of the pulse wave is no criterion of the actual height of the blood pressure, for it may be low with a high blood pressure or *vice versa*. The pulse tracing or *sphygmogram* (p. 151) can give no absolute or quantitative information regarding any phase of the arterial blood pressure. It is merely a record of the movements of the vessel walls brought about by pressure variations. The movements of the wall of a peripheral artery are very slight, but in the sphygmograph tracing they are magnified several times. When the pulse is felt by the finger placed upon the radial artery it is the pressure change—the impact of the pulse wave—rather than the actual movement of the vessel wall which is detected.

the time the wave takes to pass any point. The manner of obtaining V has been described above. T may be obtained from the time markings on the pulse tracing or simply from the pulse rate. If, for example, 70 pulses pass a point in the artery per minute, each must require $\frac{6}{7}$ second for its passage.

FIG. 51. Motion in a water wave. Nine equidistant water particles are represented by dots. The particles move in vertical circles with fixed centers, all with the same uniform velocity. The position of each particle in its orbit is called the *phase* of its motion. In the diagram each particle differs in phase from the next by one-eighth of a full revolution. At the top of the circle each particle moves in the direction of travel of the wave (as indicated by the large arrow); those towards the bottom move in the opposite direction. The particles upon the crests of the wave, a and i , are the same phase and in a phase opposite to that of e , in the trough of the wave. After the wave has passed the particles come to rest and may show no change from their original positions. The length of the wave is the distance between two particles in the same phase. (Modified from Kimball's *Textbook of Physics*.)

FIG. 52. Diagram representing a pulse wave passing over an artery. Heavy double line, artery at rest; dotted line, artery expanded. Curves X, Y and Z are drawn during the passage of the wave (in the direction indicated by the arrow) by three levers placed upon the vessel at x , y , z . At Z the greater part of the wave has passed beneath the lever at z , as shown by the continuous line of the first curve, and has still to describe the smaller part represented by the broken line. In Y the lever at y is at the summit of the wave. At X the lever x has just commenced to rise and the greater part of the curve has still to be inscribed as indicated by the dotted line (after Foster).

Analysis of the pulse curve

The pulse wave may be made to describe a curve by laying a light lever upon an artery, e.g., the radial, and having it record its excursion upon a moving surface as the artery expands and recoils beneath it. The means of doing this is provided by an instrument known as a *sphygmograph*. One of the best known of these is Dudgeon's shown in figure 53. The curve consists of an abrupt almost vertical upstroke, the *anacrotic limb*, and a more

gradually sloping downstroke, the *catacrotic limb*. The rising limb is inscribed first and represents the front of the pulse wave, while the catacrotic limb is drawn during the fall of the lever, i.e., after the crest of the wave has passed. Though under abnormal conditions of the circulation (see below)

FIG. 53. Dudgeon's sphygmograph, applied to the radial artery.

FIG. 54. The pulse wave. A. Primary wave, B. Dicrotic notch, C. Dicrotic wave.

FIG. 55. Abnormal pulse curves. 1, aortic stenosis, 2, aortic regurgitation, 3, arterial hypertension, 4, arterial hypotension.

the anacrotic limb may show one or more secondary waves, it is under ordinary circumstances smooth and uninterrupted. The descending limb, on the other hand, shows a well-marked negative wave, i.e., a depression, followed by a positive wave. These are known as the *dicrotic notch* and *dicrotic wave*, respectively. Under certain conditions the

dicrotic wave may be so well-marked that it can be felt as a separate impulse by the finger placed upon the radial artery. Often less well-marked wavelets preceding the dicrotic notch (*predicrotic waves*) are present. Other waves (*postdicrotic*) may follow the dicrotic wave (fig. 54).

The dicrotic wave and notch are produced in the following way. As ventricular systole comes to an end and the intra-ventricular pressure falls below the aortic, pressure eddies bring the aortic valves into apposition; at the same time the distended elastic arterial wall rebounds and pressing upon the blood forces it centrally as well as thrusting it forward toward the periphery. The swing of the blood column toward the heart sets up a

charge, (b) the output per beat, (c) the height of the diastolic pressure and (d) distensibility of the arterial walls. With a slow rate of ejection such as occurs in narrowing of the aortic ring (stenosis) the upstroke is gradual, the wave usually of low amplitude and a secondary fluctuation may appear (anacrotic wave) which in some instances is actually higher than the primary wave (fig. 55, 1). Secondary waves upon the anacrotic limb are also found in aortic aneurysm or when the aorta is narrowed as a result of a developmental defect or by pressure from without. These waves on the anacrotic limb are probably reflected from the periphery of the circulation, the long period of ejection permitting waves to travel centrally and meet the primary wave before it has reached its crest. When the discharge is rapid, the output large, or the

FIG. 56. Tracing showing the difference between the subclavian (central) and radial (peripheral) pulse in man. The delay of the radial pulse is clearly shown (after Wiggers).

negative fluctuation which is propagated in the wake of the main or primary wave throughout the arterial tree and is represented by the dicrotic notch on the pulse tracing. The next instant the aortic valves which have been forced toward the ventricular cavity become taut, the movement of the blood column is abruptly checked and rebounds from their surfaces. This sets up a positive pressure change which appears in the pulse tracing as the dicrotic wave.

Variations in the form of the pulse curve

The slope of the *ascending limb* is dependent upon several factors, (a) the duration of the ventricular dis-

charge, (b) the output per beat, (c) the height of the diastolic pressure and (d) distensibility of the arterial walls. With a slow rate of ejection such as occurs in narrowing of the aortic ring (stenosis) the upstroke is gradual, the wave usually of low amplitude and a secondary fluctuation may appear (anacrotic wave) which in some instances is actually higher than the primary wave (fig. 55, 1). Secondary waves upon the anacrotic limb are also found in aortic aneurysm or when the aorta is narrowed as a result of a developmental defect or by pressure from without. These waves on the anacrotic limb are probably reflected from the periphery of the circulation, the long period of ejection permitting waves to travel centrally and meet the primary wave before it has reached its crest. When the discharge is rapid, the output large, or the

diastolic pressure low, the pulse wave tends to be of large amplitude and its upstroke steep (fig. 55, 4). The slope of the *descending limb* is abrupt when the diastolic pressure is low as in aortic regurgitation or arterio-venous aneurysm (fig. 55, 2). Any state which renders the arterial walls less tense will tend to increase the magnitude of the dicrotic fluctuations and to produce other secondary waves (predicrotic and postdicrotic) which under ordinary circumstances do not appear. If, for example, the arterial system is underfilled, as a result of haemorrhage or vasodilatation, or a low diastolic pressure from whatever cause exists, the dicrotic wave becomes prominent; under such conditions as in typhoid fever, it may sometimes be felt with the finger as a distinct tap following the primary wave. The pulse is then said to be dicrotic.

THE PULSE WAVE IN DIFFERENT REGIONS.

CENTRAL ARTERIAL PULSE

Pulse tracings recorded at different parts of the arterial tree show that the conformation of the wave changes as it travels toward the periphery. The rise and fall of the primary wave are more gradual and the amplitude is less in the smaller arteries. A pulse curve taken from a central artery such as the subclavian differs very strikingly from the typical tracing taken from a peripheral artery such as the radial. Instead of the usual comparatively shallow dicrotic notch and rounded wave, a sharp depression (*incisura*) followed by a sharp spike is seen in the subclavian tracing. Such a record may be obtained from the human subclavian by means of a small conical cup pressed into the supraclavicular fossa and connected with an optical recording apparatus (fig. 56). A *central arterial pulse* shows two preliminary vibrations. These immediately precede the main upstroke, i.e., they occur before the opening of the semilunar valves, and result from pres-

sure changes transmitted through these delicate structures. The first (a-b) is due to auricular systole; the second (b-c) to the tension developed at the beginning of ventricular systole (isometric period, p. 172). The ejection of blood from the ventricle causes a sharp rise in pressure which, setting the blood column into vibration causes the fluctuations c, d, e. The pressure mounts to f and is sustained for a time, but then as systole comes to an end it drops precipitately to produce a deep depression—the *incisura* (g-h). This occurs during the closure of the semilunar valves and corresponds to the so-called protodiastolic period of ventricular diastole (p. 173). Several waves follow the *incisura*, due to after-vibrations of the valves. In their transmission through the arterial wall to peripheral points minor fluctuations of the central pulse become fused to produce smooth contours, while the primary oscillations, the *incisura*, and the after vibrations become dampened down and appear eventually as the primary wave and dicrotic fluctuations of the distal arterial tracings.

CHAPTER XIX

THE PHYSIOLOGY OF CARDIAC MUSCLE. PERFUSION OF THE ISOLATED HEART

HISTOLOGY OF CARDIAC MUSCLE

Cardiac muscle fibers, like those of voluntary muscle, have transverse as well as longitudinal striations. But the investing sarcolemmal sheaths of the cardiac fibers, unlike those of skeletal muscle are ill-defined and the muscle cells communicate with one another through branches or bridges of protoplasm (fig. 57). So, the cardiac muscle, rather than being a collection of separate fibers, has the characters of a syncytium—a continuous multinucleated sheet over which an impulse may spread without interruption in any direction. The cross striations are less distinct than in skeletal muscle, the sarcoplasm is more abundant and the nuclei are embedded in the center of the cell.

THE PHYSIOLOGICAL PROPERTIES OF HEART MUSCLE

These may be considered under the following heads: (1) *Excitability and contractility*, (2) *rhythmicity*, and (3) *conductivity*.

(1) *Excitability and contractility*

The ability of a tissue to respond to a stimulus is spoken of as excitability or irritability. In the case of muscle the response is a shortening of its fibers. Certain features of the contraction of cardiac muscle will now be discussed.

(a) THE "ALL OR NONE" LAW. This states that the weakest stimulus that is capable of causing a contraction at all (minimal stimulus) will produce the maximal contraction. This fundamental fact, which was first demonstrated by Bowditch in 1871 in cardiac muscle, has since been found to be true also for nerve and skeletal muscle. Though a skeletal muscle responds to stimuli of graded strengths by contractions of graded amplitude and so apparently differs from cardiac muscle, it can be shown that a single skeletal fiber obeys the "all or none" law. The apparent difference in behavior between cardiac and skeletal muscle is due to the fact that the former is a continuous protoplasmic sheet, and an impulse which causes contraction in one part spreads under ordinary circumstances and involves the whole. The individual fibers in skeletal muscle, on the other hand, are insulated from one another. The graded response of the *entire* skeletal muscle means simply that more

fibers are excited by the stronger than by the weaker stimulus.

It must be pointed out that a minimal stimulus at one time may at another be subminimal should the excitability of the muscle be reduced. On the other hand, should the excitability be increased an ineffective stimulus may be rendered effective. Consequently, when it is said that the cardiac muscle follows the "all or none" law it is to be remembered that this applies only to the conditions existing at the time. The excitability and contractility of the muscle is variable and a stimulus which under one set of conditions would produce a weak contraction would under more favorable conditions produce a much greater response. Length of the fiber, hydrogen ion concentration, state of nutrition, fatigue and the inorganic constitution of the fluid bathing the heart (p. 157) are among the factors which influence its excitability and the force of its cardiac contraction.

(b) TREPPE. This phenomenon was also first observed by Bowditch in cardiac muscle, though it is also shown by skeletal muscle. If a number of stimuli of the same intensity (maximal) be sent into the muscle after a resting period, the first few contractions of the series show a successive increase in amplitude. This ascent in the magnitude of the responses at the beginning of the series suggests the rising steps of a stair case (German *treppe*) and is supposed to be due to the greater contractility of the muscle at this time, resulting from the rise in temperature and the slight increase in H ion concentration of the muscle as a result of lactic acid production. This apparent contradiction of the "all or none" law is explained by the considerations in the foregoing paragraph.

(c) THE REFRACTORY PERIOD. The refractory period of skeletal muscle is very brief (0.01 second) and corresponds to the latent period, i.e., the period elapsing between the receipt of the stimulus and the commencement of the contraction. A stimulus applied to the muscle any time after it has commenced to contract causes a second contraction which is added to the first (*summation*). A rapid series of stimuli timed to fall in each instance just after the refractory period of the preceding contraction will produce a rapid series of

shortenings of the muscle which fuse into an apparently maximal contraction (*tetanus*). The contraction is sustained as long as the stimulation is continued or until fatigue sets in. Heart muscle behaves differently. Its refractory period is relatively long and lasts throughout the contraction phase. *The muscle will not respond to a second stimulus, no matter how strong, so long as its fibers are still in the contracted state.*¹ This is the *absolute refractory period*.

The time interval following a previous excitation during which stimulus will not elicit an impulse of sufficient intensity to be conducted through the cardiac muscle is termed by Drury the "*effective refractory period*."

During relaxation the muscle regains its excitability gradually. Early in the relaxation phase

FIG. 57. Cardiac muscle fibers

the strength of stimulus required to produce a response is greater and the response to a given stimulus is less than later on. Not until complete relaxation has occurred does the excitability of the muscle return to its normal value. This period of time during which excitability is depressed but not abolished is called the *relative refractory period*. The latent period of the response, that is, the time elapsing from the application of the stimulus to the contraction of the ventricle, is the same whether the latter is induced early or late in the relative refractory period (Woodsworth, Fiddes). The lengthening of the latent period found by Marey and illustrated in his tracing (fig. 58) was apparently due to inadvertent stimulation of the auricle

¹ Wiggers finds that the refractory period of the heart does not last for the entire duration of its contraction but that it responds by a contraction early in diastole to a stimulus applied within the last 0.06 seconds of systole.

by the leakage of current from the electrodes applied to the ventricle. The variability of the latent period in these classical experiments is therefore considered to be of supraventricular origin.

It will be noted from a reference to figure 57⁵⁸ that a long pause follows the contraction caused by the artificial stimulus. The artificially induced contraction is called an *extra systole* or *premature contraction*. The long interval following the *extra-systole* is termed the *compensatory pause*

FIG. 58. Myograms of frog's ventricle, showing effect of excitation by break induction shocks at various moments of the cardiac cycle. The line 0, 0 indicates in all tracings the commencement of the beats during which the shocks were sent in. It will be noted that in 1, 2 and 3 the heart is refractory to the stimulus. The signal (the break in the horizontal line) indicates the moment at which the stimulus was applied. The latent period (hatched area) does not alter as this figure shows. See text. The extrasystoles increase in height from 4 to 8, each being followed by a compensatory pause (after Marey).

since its duration is such that when the next normal beat is resumed it occurs at precisely the same time, i.e., at the same point in the tracing, as it would have appeared had no premature contraction been provoked. The occurrence of the long pause is explained as follows. The normal impulses pass from the auricle to the ventricle in a perpetual stream and in orderly sequence. When the ventricular muscle is stimulated artificially during diastole, and an extra contraction induced, the normal impulse when it arrives from the

auricle at the usual time finds the ventricle already in the contracted state and, in consequence, refractory. The impulse is therefore ineffective. Not until the arrival of the next normal impulse is the muscle in a condition to respond.² This accounts for the fact that the time elapsing between the normal beats preceding and following, respectively, the premature contraction is equal to the length of two normal cardiac cycles. In other words, the heart after the interruption in its rhythm again "gets into step."

The long refractory periods of the cardiac muscle serve to preserve the cardiac rhythm. The absolute refractory phase makes the summation of contractions and the production of tetanus impossible. The relative refractory period tends to discourage the occurrence of a second contraction before sufficient time has elapsed to allow the complete relaxation of the muscle from a preceding contraction. When a premature contraction does occur its refractory period serves to restore the normal rhythm.

The absolute refractory period may be altered by various agencies. It is shortened by rise in temperature and rapid heart action (see p. 200). It is prolonged by the action of certain drugs (p. 202). Vagal stimulation shortens the refractory period of the auricular muscle but has no effect upon that of the ventricular muscle (p. 202).

(2) *Rhythmicity and (3) conductivity*

These properties of cardiac muscle will be considered in subsequent pages.

Cardiac tonus

The subject of tonus in mammalian cardiac muscle has been beset with conflicting opinions.

² Sometimes when the premature contraction occurs early in diastole, being very weak and short it is over before the next normal impulse arrives. Therefore a long pause does not appear. An extra contraction situated between two normal beats and not followed by a long pause is called an *interpolated extra-systole*. The underlying processes responsible for the refractory periods, absolute and relative, are unknown. They have, however, been given a somewhat picturesque explanation based upon the assumption that the cardiac contraction results from the liberation of energy accumulated during the diastolic period. During systole this energy is "touched off" by the cardiac impulse and discharged. At the end of the contraction phase it has been completely dissipated, a second stimulus is therefore ineffective. In early diastole a relatively small amount of energy has accumulated and a stimulus applied at this time in consequence calls forth a very weak response. Subsequent responses correspond to the amount of energy built up, between the previous systole and the application of the stimulus. This conception is useful for purposes of illustration but it gives little aid in gaining an insight into the fundamental processes concerned.

Rhythmical tonus changes were demonstrated by Fano in the auricle of the tortoise. This observation has been repeatedly confirmed, yet it should not be cited in support of the view that tonus is a property of the mammalian heart since the rhythmic changes were shown by Bottazzi to arise in a sheet of smooth muscle lying beneath the endocardium and not in the cardiac fibers proper. Tissue of this nature is absent from the warm-blooded heart and from the ventricle of cold-blooded animals. Tone in the ventricles of the latter as well as in either chamber of the mammalian heart has yet to be demonstrated.

A great deal of confusion has arisen regarding the question of cardiac tone, through different interpretations having been given to the term itself. Tonus of muscle in the usual physiological sense means that state of partial and sustained contraction by which the muscle offers resistance to being stretched above or in addition to that which is offered by its purely physical properties. For instance, a skeletal muscle at rest and in connection with the central nervous system exhibits a slight but definite and persistent contraction. Less force is required to lengthen it when the nerves are cut and the tonic contraction disappears. The resistance which the muscle offers after this is dependent purely upon its inherent physical qualities, such as may be possessed by non-viable material, e.g., an elastic band.

With regard to the muscle of the heart the question is this. During diastole, does a certain degree of slight contraction—tonus—persist which offers some resistance to the inflowing blood and in consequence influences at this time the length to which the fiber is stretched? There is little definite evidence that tonus in this sense is possessed by the mammalian heart muscle; but variations in extensibility of cardiac muscle are admittedly more difficult of investigation than are those of skeletal muscle. In the intact heart the only means available for such a determination is the detection of a change in the volume of the heart when a single experimental condition which might be expected to affect tonus is altered while all other factors are kept at constant values. The capacity of the ventricular cavity can increase only, of course, by a lengthening of the cardiac fibers, therefore the volume of the ventricle during diastole (diastolic volume) will give during this period an index of fiber length. Variations in the latter can be taken to represent tonus changes only when other influences which will affect the diastolic volume are eliminated. For instance, increase or decrease in the venous return during the experiment would alter the fiber length; variations in the duration of diastole would also influence the diastolic volume, since more blood will flow into the ventricle during a long than during a short diastolic period. These factors must therefore be adequately controlled before justifiable conclusions concerning tonus changes can be drawn. Apparently the constancy of the experimental condi-

tions has not always been assured and erroneous judgments upon cardiac tonus have been pronounced.

Evidence of tonus changes derived from the action of drugs upon the heart are inadmissible since abnormal conditions may be thereby induced.

It has been customary to use the term "tone" somewhat loosely, and to refer to a heart showing a large or small diastolic volume as possessing "low tone" or "high tone" respectively. But as just stated the difference in volume may be the result of other factors and need have nothing to do with tone.

PERFUSION OF THE ISOLATED HEART; NUTRITION AND OXYGEN REQUIREMENT OF THE CARDIAC MUSCLE

The frog's heart possesses no circulatory system, but merely obtains its oxygen and the necessary nutrient materials from the fluid which bathes it. In order to perfuse successfully the excised heart of higher animals certain special conditions must be fulfilled. When this has been done the mammalian heart (not excepting the heart of the human subject excised shortly after death) may continue to beat for several hours.³

The following requirements must be satisfied in carrying out the perfusion of the mammalian heart.

(1) Pressure

It is essential that the perfusion fluid be delivered under sufficient pressure in order to drive it through the coronary circulation. This is accomplished by means of a reservoir raised to a height equivalent to the normal aortic blood pressure (i.e., about 5 feet). Following the method of Langendorff a cannula is tied into the aorta. The heart is allowed to hang from the cannula which is fixed to a support and connected by tubing to the supplying reservoir. The aortic valves are brought naturally into apposition by the pressure of the fluid, which then enters the coronary arteries. Little or no fluid enters the left ventricle from the aorta; after completing the coronary circuit it escapes into the right auricle by the coronary sinus. A smaller amount enters the ventricles through the veins of Thebesius and other channels (p. 274).

(2) Temperature

The perfusion fluid is maintained at body temperature by passing it through a glass or metal worm immersed in a water bath whose temperature

³ Mann and his colleagues have succeeded in transplanting the heart from one dog to another and having it beat regularly for eight days.

may be regulated by a thermostat. Increase or decrease in temperature causes a corresponding change in heart rate. The rate of the frog's heart is doubled by a 10°C. rise in temperature between 4° and 20°C. That is, the temperature coefficient is about 2 (fig. 59). A corresponding relationship between heart rate and temperature holds for the mammalian heart within the temperature range from 26° and 40°C.

(3) Oxygen supply

This is furnished by bubbling oxygen or compressed air through the perfusion fluid. The oxygen consumption of the heart in a heart-lung preparation under conditions approximately those of bodily rest was found by Evans and Starling to

FIG. 59. Showing the linear relation of temperature to heart rate over a range of about 30°C. in South African frog (Taylor).

average 3.24 cc. per gram of heart tissue per hour. The oxygen consumption of the isolated heart is probably much less than this. During maximum work, on the other hand, the heart of the intact animal probably consumes oxygen at the rate of 40 cc. or more per gram per hour. Experiments with the heart-lung preparation show that the oxygen usage is directly proportional to the work performed by the heart, which in turn runs parallel with the length of the muscle fiber (p. 217). The oxygen consumption of the heart is greatly increased by the addition of adrenaline to the perfusion fluid. The efficiency of the heart is also increased by adrenaline in physiological dosage.

Cardiac muscle is capable of contracting only a small oxygen debt (p. 618) and ceases to function

normally when the latter amounts to 0.06 cc. per gram of tissue, that is, about a fifth of the debt which skeletal muscle can contract (0.30 cc. per gram). The heart muscle is highly sensitive to changes in pH and has a much lower buffering power than has skeletal muscle. As a consequence, when the lactic acid reaches a concentration of about 0.07 per cent in heart muscle extra-systoles, heart block or other irregularities occur, followed by cessation of the beat. Skeletal muscle, on the other hand, continues to contract until a lactic acid concentration of over 0.2 per cent is reached. The mammalian heart is unable to do work for more than 5 or 10 minutes after its oxygen supply has been cut off.

(4) Chemical constituents

Blood serum or defibrinated blood, or whole blood to which hirudin or heparin has been added may be employed as the perfusion fluid. An artificial fluid, however, is frequently used but it must imitate the plasma in so far as the chief inorganic salts of the latter are concerned.

Such a solution is that first devised by Ringer, who drew attention to the importance of the three cations, Na⁺, K⁺ and Ca⁺⁺ in the same proportions as they exist in plasma, for the maintenance of the normal action of the heart.

Ringer's solution contains the three elements in the form of the chlorides of sodium, potassium and calcium. Several modifications of this original fluid have been made. *Locke's* solution, for instance, contains in addition *sodium bicarbonate* and *glucose*. *Tyrode's* solution is similar to the former but also contains a small percentage of *magnesium chloride* and of the *acid* and *sodium phosphates*. The phosphates are designed to give the solution an optimum concentration in H ions. Table 15 gives the percentage compositions of the three different fluids. The nitrogenous constituents of blood serum, e.g., proteins, urea, etc. apparently have little effect upon the beat.

Clarke found, however, that a frog's heart after perfusion for some hours passed into a "hypodynamic" state. Contraction and conduction became greatly impaired. This condition was attributed to the removal of lipid materials from the muscle cells. The addition of certain lipid materials partially restored the heart to its previous condition.

The actions of the different cations upon the heart beat

Ringer observed that if the heart were perfused with 0.6 per cent sodium chloride solution a few beats were executed, but the heart then stopped in diastole. The addition of calcium restored the

beat for a time but the heart again came to a standstill, this time in systole. The addition of potassium antagonized the calcium effect; the beat recommenced and was maintained.

It is now well known that calcium in excess, or in normal concentration, but in the absence of potassium, lengthen systole at the expense of diastole. The heart finally stops in the fully contracted state—*calcium rigor*. Potassium acts in a reverse manner if in excess or unbalanced by calcium. More and more of the cardiac cycle is occupied by diastole and the heart ultimately comes to rest in the completely relaxed state—*potassium inhibition*. A solution containing calcium and potassium alone will not sustain the beat; sodium is essential. The manner in which sodium acts is not so clearly demonstrable as in the case of the other cations, but it is certain that the

TABLE 15
Percentage composition of perfusion fluids

	RINGER'S (MODIFIED FOR MAMMALIAN HEART)	LOCKE'S	TYRODE'S
NaCl.....	0.900	0.900	0.900
KCl.....	0.030	0.024	0.02
CaCl ₂	0.025	0.042	0.02
MgCl ₂			0.01
Glucose.....		0.1	0.1
NaHCO ₃	0.020	0.020	0.1
NaH ₂ PO ₄			0.005

excitability and contractility of the heart muscle cannot be maintained in its absence.

It is apparent than that these three cations are absolutely necessary for the normal beat of the heart, the calcium increasing the contractility and prolonging systole. Potassium has the reverse effect, reducing contractility and favoring relaxation. The presence of these substances in proper proportion ensures the rhythmicity of the contractions. It would appear, however, that potassium is of less importance than the other two, since the turtle's heart will beat for a time when this ion is absent. On the other hand, this may simply be due to the well known fact that the muscle cells have themselves a rich store of potassium. With regard to other bivalent cations, strontium, though less efficient, can replace calcium in the perfusion fluid, but barium is toxic, and magnesium is inert.

Of the underlying physical or chemical changes through which these elements influence the heart beat little is definitely known. Calcium decreases and potassium increases the permeability of the cell mem-

brane. According to some, the excitability and contractibility of the muscle fiber is dependent upon the relative concentrations of H ions on the two sides of the cell membrane. The Ca and K ions through altering the cell permeability may in this way affect the diffusion of H ions across the membrane and so vary their relative concentrations on the two sides.

The effect upon the heart beat of changes in the reaction of the perfusion fluid

Acids when added in *moderate* excess act like potassium in that they favor relaxation of the cardiac muscle. The heart finally comes to rest in diastole. Alkalis, on the other hand, serve to prolong systole and shorten diastole. In this way they act like calcium. Acids depress and alkalis increase conductivity through the auriculo-ventricular bundle (p. 163). Andrus and Carter found that when the pH of the fluid perfusing the isolated mammalian heart was reduced to 7.0 complete heart block occurred (p. 213).

The higher tension of carbon dioxide during muscular exercise probably exerts a beneficial effect at this time upon cardiac behavior. During exercise the blood flow through the muscles is greatly augmented and a larger volume of blood is returned to the right side of the heart; the rise in carbon dioxide tension will favor more complete relaxation of the cardiac muscle for the accommodation of the greater load of venous blood.

The metabolism of cardiac muscle

From experiments in the past it had been concluded that the heart muscle derived energy by the direct utilization of blood sugar, since glucose disappeared from blood perfusing a heart-lung preparation, or from fluid used to perfuse the isolated heart. Figures ranging from 0.8 to 5.3 mg. per gram of heart muscle per hour have been obtained by different observers for the quantity of glucose removed by the heart. It has been shown, however, that a rapid breakdown of glucose (glycolysis) with the production of lactic acid occurs in blood after its removal from the body, i.e., free from contact with any tissue. Evans and his associates found that lactic acid was produced, as a result of glycolysis, at the rate of about 14 mg. per 100 cc. of blood per hour. Glycolysis also occurs in an artificial perfusion fluid as a result of bacterial action, and it has been shown that if rigid precautions are taken against bacterial growth, relatively small quantities of glucose disappear from fluid used to perfuse the excised heart.

The work of McGinty and of Lovatt Evans and their associates indicates that the heart muscle does not utilize glucose directly or does so to a minor extent. On the other hand, the heart removes relatively large amounts of lactic acid from the blood. McGinty and Miller analyzed the ingoing (arterial) and outgoing

(venous) blood of the coronary system of the beating heart *in situ*, and found that 0.39 mg. of glucose and 3.1 mg. of lactic acid per gram of heart tissue per hour disappeared. They concluded that glycolysis alone accounted for the loss of glucose none of which was actually absorbed by the heart muscle. Comparable results were obtained by Evans and his associates in their earlier experiments but in a more recent study they found that glucose was also consumed by the heart muscle though to a much less extent than was lactic acid. According to these workers, the blood lactic acid of the intact resting animal is derived from the breakdown of glucose in the lungs and in the blood itself. The lactic acid is removed, apparently oxidized, by the heart muscle and other tissues. During strenuous muscular exertion lactic acid is produced in large quantities in the active muscles and passing into the blood is removed in the same way (p. 619). Though glucose as well as glycogen and lactate is burned by the heart muscle, it is used mainly to restore the glycogen stores. Bogue and his associates found that the heart's glycogen store is rapidly depleted by the administration of adrenaline. The glycogen can be reformed again from glucose but not from lactate.

Fletcher and Waters, employing the heart-lung preparation perfused with heparinized blood containing no glucose (washed corpuscles in plasma previously fermented with baker's yeast) and a very low lactic acid concentration, found that in a heart performing moderate work over a 2 hour period no demonstrable reduction of the glycogen stores occurred, nor was there any diminution in the concentration of blood fat. From the results of other workers (Cruickshank and McClure) it appears that the mammalian heart does not utilize amino-acids as a source of energy to any important extent. The results of Fletcher and Waters' experiments indicate therefore that the heart can derive its sole energy requirements when necessary from non-carbohydrate material, most probably fat, composing its substance. These workers suggest that glycogen is used only as an emergency fuel, that is, when heavy work is undertaken. Evidence for the utilization of fat by the cardiac muscle has been furnished by the work of Cruickshank and McClure and by Visscher. Under certain conditions only a small fraction of the oxygen consumed by the heart can be accounted for by the oxidation of carbohydrate food (lactic acid and glucose), the balance being used presumably in the combustion of fat. On the other hand, with a high blood sugar the respiratory quotient (p. 523) may be 0.95 or 1.0, indicating a high carbohydrate utilization. The conclusion to be drawn from the results of the work of the various investigators in this field, is that the heart muscle shows a great adaptability in the utilization of different food materials. When lactic acid, glucose and fat are available all three may serve as sources of energy.

With regard to the chemical changes occurring in the cardiac muscle during activity, it may be said that for the frog's heart at least, and perhaps also for the mammal's, they are, in general, closely similar to those

taking place in skeletal muscle (p. 612). Phosphocreatine is broken down and lactic acid produced during anaerobic activity. The energy derived from the latter reaction is used for the resynthesis of phosphocreatine. In the recovery phase (diastole) a part of the lactic acid, it may be presumed, is resynthesized to glycogen and the remainder oxidized.

In the asphyxiated *frog* heart the phosphocreatine content of the muscle gradually diminishes and cardiac arrest occurs in about 15 or 20 minutes when all but about $\frac{1}{4}$ of the phosphocreatine store (which is only $\frac{1}{10}$ that of skeletal muscle) has disappeared. Readmission of oxygen brings about recovery and the restoration of the original phosphocreatine content. When poisoned with iodoacetic acid in the *absence* of oxygen, depletion of phosphocreatine occurs more rapidly, and the heart is arrested in from 2 to 4 minutes, but in the presence of oxygen the poisoned heart will continue to beat normally for an hour or so with no diminution of its phosphocreatine content. This indicates that the contractions of the frog's heart are not solely dependent upon the mechanism in the carbohydrate cycle upon which the drug acts (p. 614). All in all, phospho-

creatine would appear to be of much less importance as a source of energy for cardiac activity than for the contraction of skeletal muscle, the heart continuing to beat (provided that the lactic acid is removed by perfusion with an alkaline fluid) after its phosphocreatine content has been very greatly reduced. The mammalian heart (rabbit auricle) fails, however, when the phosphocreatine loss is much less. Yet the difference in this respect between the warm-blooded and cold-blooded hearts may be due simply to the former's greater frequency of beat (300 per minute of rabbit auricle) which is ten times that of the frog's heart. One would expect that, owing to the longer recovery period of the cold-blooded heart, it would not require such a large reserve of phosphocreatine. On the other hand, when the results of experiments on the amphibian and mammalian hearts are compared, several other discrepancies become apparent which suggest that the metabolism of the two may be fundamentally dissimilar; caution must be exercised in applying to the mammalian heart the chemical findings in experiments upon the heart of the frog.

CHAPTER XX

THE ORIGIN AND MODE OF TRANSMISSION OF THE HEART BEAT

If the heart of the frog is watched as it beats, waves of contraction may be observed to commence in the sinus region and pass over the auricle to the ventricle in orderly sequence. This wave of contraction is referred to as the beat of the heart. We know that the visible contraction is preceded by a measurable interval of time by an electrical change. Also, physico-chemical changes whose precise nature is unknown, undoubtedly precede or accompany the changes in electrical potential. These electrical and chemical changes which sweep over the heart in advance of the mechanical change are spoken of as the *cardiac impulse* or *excitation wave*.

HISTORICAL. Though Harvey (1628) studied the movements of the heart and discovered the circulation of the blood, he offered no explanation for the origin of the beat. Lower (1631-1691) thought that the beat was initiated by animal spirits which were supplied to the cardiac muscle through the vagus nerves. In the eighteenth century Haller, who observed that the spread of the contraction and the flow of blood through the chambers of the heart were events which proceeded hand in hand, concluded that the contact of the blood with the cardiac tissue at successive points was the direct stimulus for the muscular contraction. The contraction was looked upon as a simple peristaltic wave. Haller also pointed out that the right auricle was the last part of the heart to cease beating—the *ultimum moriens*—a fact consonant with his theory, since this chamber usually contained more blood at the time of death than other regions of the heart.

The latter view concerning the cause of the heart-beat was held until it was found that the excised heart would beat though its chambers were quite empty. It was then realized that whatever started the beat must arise within the heart itself. But other questions arose. Was the beat initiated by nervous tissue (ganglion cells) within the heart and carried to all its parts by nerve fibers or was the power of rhythmical contraction inherent in the muscle fiber? Two opinions have been held as to how these questions should be answered. One school, the *myogenic*, adhered to the view that the muscle fiber itself initiated the impulse. The other, the *neurogenic*, maintained that the impulse had its origin in nerve cells scattered among the muscle fibers and was conveyed for shorter or longer distances by nerve filaments. Support was given to the latter view by the discovery of three groups of ganglion cells in the frog's heart which were placed at what appeared to be strategic

points for the control of the beat. These groups of cells are known respectively as the *ganglia of Remak, Ludwig and Bidder*. The ganglion of Remak lies in the sinus venosus at its junction with the right auricle. Ludwig's ganglion is situated in the interauricular wall and Bidder's in the auriculo-ventricular groove. According to the neurogenic hypothesis Remak's ganglion was a nerve center which sent motor impulses to the cardiac muscle much as the respiratory center emits automatically a stream of impulses to the diaphragm and the other muscles of respiration. The other two centers were considered more or less subsidiary to this main one and to aid in the coordination of the beat.

THE FIRST AND SECOND STANNIUS LIGATURES. Stannius (1852) showed that if a ligature were tied tightly around the heart of the frog or turtle at the junction of the sinus with the auricle, the heart below the ligature ceased to beat though the rhythm of the sinus remained unaltered. After a time the auricles and ventricles recommenced to beat but at a different rate than the sinus. If while the ventricle was under the influence of the first ligature a second one were tied around the auriculo-ventricular groove the ventricle at once commenced again to beat. From the neurogenic point of view the following explanation seemed quite satisfactory. Stoppage of the auricles and ventricles by the first ligature was due to the injury sustained by the chief motor center—Remak's ganglion—and the removal of its influence. The second ligature re-established the ventricular beat by stimulating Bidder's ganglion. Yet an explanation based upon the myogenic conception was equally plausible. Impulses arising in the sinus musculature it was claimed were blocked by the compression of the first ligature. The auricular and ventricular muscles after a time resumed their beats spontaneously by virtue of their inherent power. The second ligature restored the beat by direct stimulation of the muscle in the auriculo-ventricular groove.

Gaskell (1881) showed that compression of the cardiac tissue not only at the sino-auricular junction, but anywhere between sinus and ventricle, as may be accomplished by a specially devised clamp (Gaskell's clamp), would cause standstill of the heart below. This is so though the tissue between the jaws of the clamp is devoid of nervous elements. The part below the clamp later commences to beat at a rate of its own. Gaskell also found that gradual compression of the tissue in the auriculo-ventricular groove stopped the contractions of the ventricle. If the ganglion cells in this region (Bidder's) were then stimulated by a needle no contractions were called forth. On the other hand,

when the muscular tissue, free from nerve cells, was pricked rhythmical beats followed. It has also been shown that the tissue of the great veins which contain no ganglion cells exhibits spontaneous rhythmicity when completely separated from the sinus. Furthermore, in the heart of the tortoise it is possible to separate the sinus and the ventricle, except for a narrow bridge of muscular tissue and a single nerve (the coronary nerve). The only nervous communication between the two chambers is by means of this nerve. If in a heart so prepared the coronary nerve be cut no change in the rhythms of sinus and ventricle occurs. On the other hand, if the nerve trunk be left intact but the muscular connection severed, the two chambers then beat quite independently of one another.

From the results of these experiments it was difficult to draw any other conclusion than that the beat of the primitive heart was myogenic. Gaskell also showed that muscular tissue in different regions of the heart possessed rhythmical powers of varying degrees. The sinus was shown to possess the greatest rhythmical power; the auricle in the region of the auriculo-ventricular junction was endowed with less and the ventricle with the least. The sinus, it was believed, originated the beat under ordinary circumstances, from here the impulse spread through the muscular tissue to the other regions of the heart. Though the sinus usually dominated the rhythm of the heart another region could, upon occasions when the function of the sinus was depressed, usurp control and develop a beat of its own.

Apparently there was no obstacle to the acceptance of the myogenic conception in so far as the amphibian or the reptilian heart was concerned, since in them the musculatures of the auricles and ventricles are continuous across the auriculo-ventricular groove. But the muscle tissue in these regions of the mammalian heart was apparently completely separated by the auriculo-ventricular ring of connective tissue. In the face of this fact there was no alternative but to believe that the transmission of the beat in higher animals was mediated by nerve fibers; and if this were so its origin in nervous tissue also must be granted.

The foregoing objection to the application of the myogenic theory to the mammalian heart was removed by the work of Kent who demonstrated the existence in rats of muscle fibers passing through the connective tissue of the A-V ring. Shortly afterwards His described in other mammals a definite bundle of primitive muscular tissue (bundle of His, or auriculo-ventricular bundle) connecting the right auricle and the ventricles. This bundle and the nodes of similar tissue in the right auricle will be presently described.

In addition to the evidence just given the following facts in favor of the myogenic theory of the origin of the beat may be cited. (a) In the embryo chick the rudimentary heart shows rhythmical contractions after 36 hours. Ganglion cells do not appear until after the 6th day. The heart of the human fetus commences to beat after 3 weeks of gestation; nervous elements do

not appear until 2 weeks later. (b) The muscular tissue of the apex is said to be free from ganglion cells yet a strip excised from this region beats rhythmically. (c) If zig-zag cuts be made in the ventricle so as to interrupt any nervous paths of transmission that might exist, the sequence of the beat is unaffected. (d) In several invertebrate hearts no ganglion cells can be demonstrated.

THE SPECIALIZED TISSUES OF THE MAMMALIAN HEART

The muscle fibers mentioned in the foregoing section which were discovered by Kent to form connections between the auricles and ventricles have subsequently been shown to belong to and form part of a special system for the origin and propagation of the beat in the mammalian heart. This system is composed of primitive muscle tissue interspersed with nerve cells and fibers. There is every reason to believe, however, that the initiation of the beat in, and its transmission through this system depends upon its muscular elements.¹

These specialized tissues comprise the following structures, (fig. 59).

The sino-auricular node

The auriculo-ventricular node

The auriculo-ventricular bundle

The branches of the bundle and the Purkinje system

(1) *The sino-auricular (S-A) node*

The sino-auricular node was discovered by Keith and Flack in 1907. It lies embedded in the muscle of the right auricle to the left of a slight ridge situated on the inner surface of the chamber and known as the *tenia terminalis*. The tenia corresponds to a shallow groove on the outer surface of the auricle—the *sulcus terminalis*—which runs downwards from a point to the right of the opening of the superior vena cava to the inferior caval opening. The situation of the node in relation to the outer surface of the auricle is therefore to the left of the upper part of the sulcus terminalis and just in front of the opening of the superior vena cava. The node extends downwards for about $\frac{1}{2}$ of an inch. It has a special blood supply. Its

¹ The muscle cells have been shown to be capable of rhythmical contraction. Also if the continuity of the tissue be interrupted the gap is subsequently bridged over with scar tissue. Regeneration does not occur and conduction is never restored; this is contrary to what one would expect if the pathway of conduction were composed of nervous tissue. When the intestine, for instance, is cut across and the cut ends sutured together the divided fibers of Auerbach's plexus regenerate and functional continuity between the nervous elements in the two segments is soon restored.

minute structure is of a neuromuscular nature consisting of striated spindle-shaped muscle fibers arranged in a plexiform manner, embedded in connective tissue and intermingled with a small number of ganglion cells and nerve fibers.

Knowing the ancestry of the node, which we shall see can be traced from the sinus tissue of the primitive heart, we may suspect its function. Just as the sinus initiates the beat and sets the pace for the cold-blooded heart so the S-A node is the *pacemaker* of the mammalian heart. There exists for this statement, however, more than presumptive evidence based upon embryological considerations. The direct experimental evidence will be considered later.

(2) *The auriculo-ventricular (A-V) node*

This was first described by 1906 by Tawara. It lies in the right auricle at the lower part of the interauricular septum, anterior to the opening of the coronary sinus and above the septal leaf of the right auriculo-ventricular valve. Its microscopical structure closely resembles that of the S-A node. Its power of impulse formation is apparently second only to that of the latter. When the S-A node is destroyed or its function depressed the A-V node may then assume the duties of pacemaker. Ordinarily a definite time interval exists between the beginning of auricular and ventricular systoles. When the A-V node initiates the impulse the interval is much shorter or may be abolished, both chambers contracting nearly or quite simultaneously, since the impulse reaches both at practically the same time. This is spoken of as *nodal* rhythm and occurs as a clinical disorder (p. 194). The S-A and A-V nodes are apparently unconnected by any tract of special tissue the two being completely separated by auricular muscle. The primitive muscle cells of both nodes make intimate connection with the surrounding muscle fibers through the intermediary of cells which are transitional in structure between those of the nodal and auricular fibers.

(3) *The auriculo-ventricular bundle, and (4) Bundle branches and Purkinje system*

It was mentioned on page 162 that following the discovery by Kent of muscular bridges connecting the auricle with the ventricle a well defined bundle of muscular tissue was described by His. This bundle runs a short horizontal course forward and to the left from its origin at the A-V node, passing over the septal leaf of the tricuspid valve to the

upper part of the interventricular septum. Here it divides into a right and left branch, each going to the corresponding ventricle. The ventricular divisions pass downwards beneath the endocardium of the septum and give off primary branches to the papillary muscles. The strands are continued beneath the lining of the ventricle and divide into innumerable filaments to form a delicate subendocardial interlacement. The muscle cells composing the ventricular branches and terminal arborizations of the system take on very special features, differing from those of the bundle stem and of the auriculo-ventricular node. The cells are much larger than in the latter situations, having a swollen appearance with large pale nuclei. These peculiar cells were described by Purkinje and had been known by his name long before their significance was recognized. Tawara's researches showed that such cells constituted the ventricular continuation of the bundle. Nervous elements are also seen among the Purkinje fibers. The anatomical researches of Abramson and associates have shown that the Purkinje system does not consist simply of a layer of interlacing fibers beneath the endocardium, as has been supposed, but penetrates deeply into the ventricular muscle.

The auriculo-ventricular bundle and its branches are demarcated from the adjacent cardiac tissue by a fairly well defined connective tissue sheath. Lhamon injected the sheath with colored fluids and found that the stem and branches were completely invested even to the finer terminations, also septa were found penetrating between the fibers to enclose individual Purkinje fasciculi.

THE DEVELOPMENT OF THE JUNCTIONAL TISSUES. The heart of lower vertebrates (frog, turtle, etc.) and the heart of the mammalian embryo possess an extra chamber—the *sinus venosus* (a, in fig. 60) which first receives the blood from the veins before it enters the auricle. In the early embryo two veins conveying blood chiefly from the upper part of the body and termed the right and left ducts of Cuvier open into the sinus. The blood passes from the sinus through an opening guarded by the *right and left venous valves* into a small ill-defined chamber, the *auricular canal* (b). The latter opens into the auricle above. Below where it forms a ring around the auriculo-ventricular junction, it is invaginated or telescoped into the ventricular cavity. This portion serves the purpose of a muscular bridge for the transmission of the impulse between the auricle and ventricle in the cold-blooded heart (p. 162). In the course of development of the mammalian heart these embryonic structures disappear but the tissue of which they are composed is believed to persist in vestigial form as the system of specialized structures

already described, namely, the sino-auricular node and the auriculo-ventricular node and bundle.

The developmental history of these several parts of the system is as follows:

(a) The line of junction of the sinus venosus with the primitive auricle is represented by the sulcus terminalis of the adult heart. The tissue of the wall of the sinus at the opening of the right duct of Cuvier (which enters into the formation of the superior vena cava) and the tissue comprising the right venous valve are represented in the adult heart by the sino-auricular node.

(b) The sinus wall in the region of the left duct of Cuvier (which becomes in part the coronary sinus) and

FIG. 60. Diagram representing the junctional tissues of the mammalian heart. 1. Superior vena cava, 2. sino-auricular node, 3. coronary sinus, 4. auriculo-ventricular node, 5. auriculo-ventricular bundle, 6. primary branches of bundle, 7. papillary muscles, 8. inferior vena cava.

the tissue of the left venous valve remains as the auriculo-ventricular node.

(c) The funnel-shaped invagination of the auricular canal is represented in the adult heart as the auriculo-ventricular bundle.

The investigations of Keith and Mackenzie suggest that the parts of the cold-blooded heart (sino-auricular and auriculo-ventricular junctions) from which the junctional tissues of the mammalian heart have apparently evolved are also of specialized neuromuscular structure (nodal tissue). According to these observers this explains the greater rhythmicity of these regions of the cold-blooded heart. The tissue is more diffuse in the hearts of lower orders, forming in these incomplete rings at the sino-auricular and auriculo-ventricular junctions, whereas in the mammal it is more localized.

The condensation becomes more pronounced as the animal scale is ascended.

EVIDENCE FOR THE ORIGIN OF THE CARDIAC IMPULSE IN THE SINO-AURICULAR NODE

(1) Heat or cold applied locally to the node, but not to other parts of the heart, causes increase or decrease, respectively, in the rate of the heart beat.

(2) Destruction or excision of the node causes the rest of the heart to stop beating for a time. Such procedures are analogous to the first Stannius experiment as performed upon the cold-blooded heart. Cohn, Kessel and Mason investigated the subject very fully in perfused hearts both inside and outside the body. They found that excisions of portions of tissue in the region of the node merely accelerated the rate. Incisions separating the node on three sides did not block the impulse. The beat ceased, however, upon completion of the rectangle by a fourth incision. The resumption of the beat in the auricles and ventricles was at a slower rate after the immediate effect of the incision (complete stoppage for from 4 seconds to 3 minutes) had passed off.

(3) In a case of complete ectopia cordis in man, the impulse has been observed to originate in the region of the sino-auricular node, and to spread uniformly from there through the auricles. The apex of the heart becomes excited slightly ahead of the base.

(4) It was shown by Lewis that a contraction induced by artificial stimulation gave an electrocardiogram (p. 180) which most closely simulated the normal when the stimulus was applied in the vicinity of the S-A node itself. Abnormal P waves appeared when any other part of the auricle was excited.

(5) The crucial experiment proving the initiation of the beat in the S-A node was devised by Lewis. By means of a pair of contacts placed in different positions upon the surface of the normally beating heart of the dog, and connected with a galvanometer Lewis demonstrated that at each beat the node was the first part of the heart to show relative negativity. (See Fig. 60A.)

In order to understand this piece of evidence it is necessary to recall some of the fundamental principles of the electro-physiology of muscle. In figure 61 I, A and B represent opposite ends of a muscle strip. Contacts placed on each end of the muscle are connected with a galvanometer, and the polarity of this is such that when B is negative to the rest of the muscle the galvanometer mirror

swings to the right, and a beam of light thrown upon a moving photographic surface causes an upright wave (positive wave) to be traced. When A is negative a reverse movement occurs and a curve is inscribed below the base line (negative wave). The two ends of a muscle at rest and uninjured have equal electric values and the galvanometer needle remains stationary when the contacts are placed in these situations. Excited or injured muscle is, however, relatively negative to muscle in the non-excited or uninjured state. When, therefore, B in figure 61 I, 1 is stimulated electrically or otherwise the muscle at that point becomes relatively negative to the rest of the muscle, a current flows within the strip in the direction of the

auricle which first became negative (primary negativity) was the S-A node. Consequently the impulse must originate within it. Contacts placed upon the beating heart always gave maximal deflections when they were situated along a line representing the radius of a circle having the S-A node as its center. Further, when the contacts were placed between the node and the ventricles—their order and the polarity of the galvanometer being as described above,—the initial deflection was upward. Finally, when one contact was placed precisely upon the node and the other placed at any point in the circumference of a circle surrounding the first, the deflections were always maximal and the first one directed upward.

FIG. 60A. Modified from Lewis. Description in text.

arrow, and a stroke above the base line of the tracing is inscribed. When the potential change associated with the excitation wave has spread over the muscle strip (fig. 61, I, 2 and 3) and involved that portion beneath contact A, the potential of the two ends is the same. The curve reaches the base line and follows it for a short distance, corresponding to the time during which this state of equal potential (isopotential) persists. The excitation wave retreats from the strip in the same order that it advanced. This, of course, will cause A, while it remains in the excited state, to become negative relatively to B. The direction of current flow will now be reversed and a wave below the base line will be inscribed (4 in figure).

Applying this method to an investigation of the auricle itself Lewis found that the region of the

THE SPREAD OF THE EXCITATION WAVE THROUGH THE HEART

The transmission of the excitation wave from the sino-auricular to the auriculo-ventricular node

The impulse is transmitted to the A-V node and across the inter-auricular septum to the left auricle through the muscular tissue. It spreads at practically equal rates in all directions; there is no tract of specialized tissue offering a pathway of "least resistance" to the auriculo-ventricular node. On this account it is difficult to produce a complete auricular blockage of the impulse. The practical uniformity of the transmission rates along different paths radiating up or down to the right or left from the S-A node has been clearly demonstrated by Lewis. Contacts were placed in series upon the

surface of the auricle or upon the great veins and the arrival of the impulse at different points accurately timed. The spread upwards through the wall of the superior vena cava was found to be an exception to the general rule, the rate being somewhat slower than in other directions. Lewis has shown that the equality of the transmission rates through the auricle has an anatomical basis. The S-A node holds a strategical position in relation to the auricular musculature. The chief muscle bands of the right auricle radiate from the region immediately below the node, termed the *concentration point*, like the sticks of a Japanese fan. The average rate of propagation of the excitation wave through the auricular muscle is 1000 mm. per second.

The transmission of the impulse from auricle to ventricle

The auriculo-ventricular node, which we have already seen forms intimate connections with the auricular fibers, forms the first link in the chain which transmits the impulse to the ventricle. The bundle, its right and left branches and the terminal arborizations of the latter constitute the rest of the transmission system. *In the mammalian heart the bundle is the sole path by which the cardiac impulse can be conveyed from auricle to ventricle.* Several investigators have demonstrated this fact conclusively by simply cutting or crushing the narrow bridge of special tissue. This is invariably followed by complete dissociation of auricular and ventricular rhythms. The cardiac disorder produced in this way is spoken of as *complete experimental heart block*. Erlanger and Blackman crushed the bundle in dogs under aseptic conditions by a specially devised clamp (Erlanger clamp). The animals lived from 320 to 340 days and during this time showed complete heart block. These experimenters showed what had not been shown before, that no other tissue could take over the duties of the bundle though the period of survival was sufficient, were it possible for such a vicarious action to be exercised. The experiment also shows that regeneration of the bundle does not take place. Epileptiform and syncopal attacks were observed in some of the animals. This is of much interest in view of the occurrence of similar manifestations in man as a result of disease of the bundle (see heart block, p. 190).

The two ventricles do not contract exactly simultaneously. Sometimes one, sometimes the other chamber precedes its fellow by one or two hundredths of a second. The interval between the

excitation of the auricles and the ventricles (A-V interval) has a duration in the human heart of between 0.012 and 0.020 seconds. The most widely accepted theory of this delay in the spread of excitation to the ventricles is the slower conduction rate of the junctional tissue (A-V node and bundle). Another view is that the delay is due to the latency of the response of the ventricular muscle or of the A-V node to the auricular impulses. Abnormally long A-V intervals (over 0.20 seconds) constitute the condition known as heart block (p. 190). Very rarely, shortening of the A-V interval to less than the lower normal limit occurs. It is due, in all probability, to the existence of an aberrant or accessory auriculo-ventricular bundle.

The spread of the excitation wave in the ventricle

The transmission of the impulse to the various regions of the ventricular musculature, right and left, is entirely by way of the His-Tawara system. Just as compression or section of the stem of the bundle causes complete functional dissociation of auricle and ventricle, so injury to one of the main (septal) branches interferes with the passage of impulses to the corresponding ventricle (p. 185, 190). The excitation wave after traversing the main branches follows the fine arborizations of the Purkinje pathway lying beneath the endocardium, and so completes a semicircular journey in each ventricle from the upper part of the interventricular system to the base of the heart. This takes 0.04 second and is at a rate of about 5000 mm. per second.

The mode of transmission of the impulse throughout the ventricular muscle is a question which has not received a final answer. Lewis' experiments indicated that the spread of the excitation was entirely through the Purkinje network lying beneath the endocardium, the impulses being then transmitted radially, i.e., by the most direct course, through the overlying ventricular muscle to the epicardial surface (see fig. 75, p. 185). In other words, the impulses, according to Lewis, did not follow the course of the muscular bundles of the heart, but cut across them by the most direct path from the endocardial to the epicardial surface. Robb and her associates, on the contrary, maintain that the impulse is transmitted from the main divisions of the Purkinje system through muscular tissue, following the direction of the muscle bundles. Abramson and others dissent from the latter view, claiming that the excitation wave reaches the individual muscle fibers via the myocardial exten-

sions of the Purkinje system (p. 163). The muscle fibers in numerous places are thus excited almost simultaneously.

The facts detailed in this chapter concerning the origin and spread of the excitation wave may now be summed up. The beat is initiated in the tissue of the sino-auricular node. From here it is "broadcast" through the auricular musculature with practically equal velocity in all directions. The A-V node acting, so to speak, as a relay station, receives the impulse and transmits it to the

ventricle via the auriculo-ventricular bundle. At the upper part of the interventricular system the pathway forks and the wave of excitation reaches each ventricle simultaneously. Its further course is through the branches of the bundle and its terminal arborizations. The mode of spread of the impulse to the ventricular muscle fibers is a debated question, but is probably through the myocardial extensions of the Purkinje system; thus different parts of the muscle are excited almost simultaneously.

CHAPTER XXI

THE CARDIAC CYCLE

GENERAL DESCRIPTION

The succession of changes which occurs in the heart and is repeated during each beat is referred to as the *cardiac cycle*. On account of the rapidity with which the events in the cycle follow one another, it is impossible to study them by mere inspection. Harvey remarked upon the difficulties of the problem.¹ Modern methods of study include the graphic registration of pressure changes within the auricles and ventricles in animals, i.e., *intra-auricular* and *intra-ventricular pressure curves*. In man, records of the *arterial* and *venous pulses* (p. 188) obtained by means of the *polygraph* or of the electrical changes—*electrocardiograms*—(p. 181) are employed in the study of cardiac action.

Before studying the intracardiac pressure curves and the methods by which they are obtained, a general account of the several phases of the cycle and their approximate time relations will be given. The contraction and relaxation of the auricles are called *auricular systole* and *auricular diastole* respectively. *Ventricular systole* and *ventricular diastole* refer to corresponding phases of the ventricular muscle. The length of the cardiac cycle, when the heart is beating at the usual rate (70 per minute), is $\frac{2}{3}$ of a second (0.86 second). Its duration, of course, varies inversely with the heart rate. The moment in the cycle when ventricular systole has just come to an end, may be chosen as the most convenient starting point for a description of the succession of events. At this time, the auricles and ventricles are relaxed. Blood is pour-

ing into the cavity of the right auricle from the venae cavae and into the left auricle from the pulmonary veins. The auricular and ventricular cavities are separated from one another by the closed auriculo-ventricular valves. The semilunar valves also have been brought into apposition, so, during this period (0.08 to 0.12 second) the ventricles are completely closed but almost empty chambers. The auricles, on the other hand, are filled with blood which has accumulated during the previous ventricular contraction, but, as the pressure in the ventricle falls below the intra-auricular pressure, the auriculo-ventricular valves are opened; venous blood under a pressure of a few millimeters of water then pours into the fully relaxed ventricles. The latter chambers continue to fill throughout the remainder of diastole, that is, for about 0.40 second, nearly half the total length of the cardiac cycle. Toward the end of ventricular filling, however, the auricle contracts and the flow into the ventricle is hastened. The right auricle contracts slightly (0.013 sec.) before the left. Auricular systole lasts for 0.1 second. As a rule no interval or a very short one (0.016 second) elapses between the end of auricular and the commencement of ventricular systole. The fall in pressure in the auricle consequent upon its relaxation, and the rise of pressure within the ventricle as it contracts closes the A-V valves. The ventricle is again for a time (0.04 to 0.06 second) a closed cavity, since the semilunar valves have not yet opened. During this period the intraventricular pressure rises rapidly. The semilunar valves are forced open and the blood is discharged into the aorta and the pulmonary artery. The pressure continues to rise but soon reaches a maximum and is maintained around this level for a short time. The ventricle then enters upon its relaxation phase; the pressure falls and the semilunar valves close again. This brings us around to the point from which we started; a cardiac cycle has been completed.

Emphasis should be laid upon the following points in the foregoing description.

(a) Blood pours into the auricles throughout the entire cycle except for the short period (0.1 second) occupied by auricular systole.

(b) Filling of the ventricle continues throughout

¹ "When I first tried animal experimentation for the purpose of discovering the motions and functions of the heart by actual inspection and not by other people's books, I found it so truly difficult that I almost believed with Fracastorius, that the motion of the heart was to be understood by God alone. I could not really tell when systole or diastole took place, or when or where dilatation or constriction occurred, because of the quickness of the movement. In many animals this takes place in the twinkling of an eye, like a flash of lightning. Systole seemed now here, now there; diastole the same; then all reversed, varied and confused. So I could reach no decision, neither about what I might conclude myself nor believe from others. I did not marvel that Andreas Laurentius wrote that the motion of the heart was as perplexing as the flux and reflux of Euripus was to Aristotle." William Harvey, "Exercitatio anatomica de motu cordis et sanguinis in animalibus," 1628.

the cycle except during its contraction and the brief succeeding period (0.08 second) which intervenes between the closure of the semilunar and the opening of the A-V valves.

(c) The ventricle contracts for about 0.30 second and rests for about 0.50 second. The auricle contracts for 0.1 second and rests for 0.7 second. The resting periods of the two chambers therefore overlap for a period (about 0.40 second) during which the whole heart is quiescent.

The following table gives the approximate figures for the duration of the chief phases of the cardiac cycle when the heart is beating at the usual rate of 70.

	seconds
Ventricular systole.....	0.3
Ventricular diastole.....	0.5
Auricular systole.....	0.1
Auricular diastole.....	0.7
Quiescent period of whole heart.....	0.4

THE GRAPHIC REGISTRATION OF INTRA-CARDIAC PRESSURES

The times of filling and emptying of the cardiac chambers, the pressures developed and the times of opening and closing of the valves guarding the orifices of the heart can be studied with great precision by this method.

MANOMETERS. The pressure changes within the heart cavities are recorded by means of optical manometers. A mercury manometer, owing to the great inertia of the column of metal, and the rapid changes in pressure which take place during the cardiac cycle, is unsuitable. The pressure in the left ventricle, for example, reaches a value of 100 mm. Hg or more within a few hundredths of a second. On account of the lag of a mercury column the amplitude of the curve obtained by a mercury manometer is considerably less than it should be, and the recorded pressure is, in consequence, less than that which actually exists; also, minor fluctuations in pressure are not registered. Tambours covered with a thin rubber membrane, upon which a light lever is fixed, have been employed with the view of overcoming these disadvantages. Marey's instrument is based upon this principle. In Hurtle's instrument, on the other hand, the pressure changes are made to bend a stiff spring, and in Fick's the curvature of a tubular spring is altered by pressure changes transmitted to its cavity. The moving parts of all these types, however, possess considerable mass and, though improvements over the mercury manometer, tend, nevertheless, through their inertia to cause inaccuracies in recording. In the *optical method* an imponderable lever, namely, a beam of light, is employed. The movements of the beam of light are recorded photographically. This

and the other methods just referred to must, of course, be calibrated against a mercury column in order to ob-

FIG. 62. I. Optical manometer for registering intra-cardiac pressure. *a*, damping plate; *b*, segment capsule; *c*, small Zeiss mirror; *d*, glass tube; *e*, brass cylinder; *f*, reflecting mirror; *g*, stopcock; *h*, conical joint for attaching different types of cannula. Enlarged view of segment capsule, see text (after Wiggers, in part redrawn).

tain quantitative results. A description of Wigger's modification of Frank's optical method follows.

The instrument (fig. 62, I and II) consists of (1) a glass tube which is introduced into the ventricle, the auricle or the aorta. The tube is surmounted by a

brass chamber (c) which can be connected or disconnected with the lower part of the tube by means of a stopcock (g), and the pressure thus transmitted to the recording part of the apparatus as required. (2) A segment capsule (b) carrying a small mirror closes the brass chamber above. (3) a moving photographic surface—plate or film.

The segment capsule (fig. 62, III) consists of a small chamber 3 mm. in diameter and circular in cross section except that a segment with a small arc has been cut off one side. The chamber is covered with a tightly stretched, thin rubber membrane. A small trapezoid celluloid plate is cemented to the surface of the membrane with the longer of its unequal sides lying flush with the chord of the capsule, while its shorter side does not extend as far as the center of the circle. The mirror is cemented in turn to the celluloid plate with its center lying precisely over the chord of the capsule upon which it pivots. By means of this device, changes in pressure transmitted to the membrane cause movements of the mirror which are greater than those of the membrane itself. The instrument is firmly clamped in position and a strong light focused upon the mirror.

FIG. 63. Auricular pressure curve. Description in text.

The beam is reflected to a second larger mirror which is adjusted to bring the ray into the horizontal plane, and have it fall ultimately upon a photographic surface moving in a suitable camera (photokymograph) across the path of the beam. The longer the beam the greater, of course, will be the magnification, though there is a limit to the length (120 to 150 cm.) which can be used advantageously.

THE INTRA-AURICULAR PRESSURE CURVE

This shows three crests (positive waves) *a*, *c*, and *v* and three depressions (negative waves) *x*, *x'*, and *y* (see fig. 63). The *first positive wave*, *a*, is caused by auricular systole. It rises fairly steeply to its summit but only represents a pressure of a few millimeters of mercury. It should be pointed out that all parts of the auricular muscle do not contract together but progressively with the spread of the excitation wave. During the rise in the *a* wave more and more fibers are entering into the excited state, tension is being developed and the auricular pressure is rising. At the summit of *a* all fibers are contracting. After this, the fibers relax also in a progressive fashion, those first excited being the first to relax and the pressure falls. The subsequent decline in pressure produces

the "negative" wave, *x*. Wiggers refers to the time during which a group of fibers remains in a contracted state as the *fractionate contraction*. The shortening of the auricular muscle as a whole is the resultant of the contracted and the relaxations. So he divides auricular systole in two phases, a *dynamic phase*, in which the proportion of the muscle fibers in the contracted state increasing and the pressure is rising to a maximum and an *odynamic phase* in which the pressure falling as a result of the fractionate contraction coming to an end in progressively greater number. The duration of each phase is about 0.05 second.

The *second positive wave*, *c*, is due to the rise in pressure in the ventricle as this chamber commences its contraction. The pressure is transmitted to the auricle through the closed A-V valves which are bulged into the upper chamber. The summit of *c* coincides with the opening of the semilunar valves.

The decline of the *c* wave and the production of the *negative wave*, *x'*, is ascribed to two factors: (a) the increase in the negative pressure within the thorax resulting from the ejection of the ventricular contents—about 60 cc. in man—from the thoracic cavity, (p. 157) (b) the drawing down of the auriculo-ventricular septum as the ventricle contracts.

The *third positive wave*, *v*, is a stasis wave. It is due to the inflow of blood from the veins and accumulation in the auricle while the A-V valves are closed. It is therefore the result indirectly, is the *c* wave, of ventricular systole.

The decline of wave *v* and the production of *negative fluctuation*, *y*, are due to the opening of A-V valves and the escape of the blood into the relaxed ventricle. A small notch which sometimes appears on the upstroke of the *v* wave near its summit is ascribed to a vibration set up by closure of the semilunar valves.

The pressure curves of the two auricles show similar features but are not perfectly synchronous. As a result of the time taken for the excitation wave to spread to the left auricle, systole of this chamber commences 0.013 second after that of the right.

The auricular contraction would appear to be of minor importance in the dynamics of the circulation, i.e., in the filling of the ventricle. This may be evident when it is recalled that the dynamic phase of auricular systole occupies only 0.05 second while the total period of ventricular filling has a duration of about 0.4 second. Also in auricular fibrillation (p. 187) in which condition the au-

certainly exert no propulsive force upon the blood, filling of the ventricle is apparently not interfered with.

THE INTRA-VENTRICULAR PRESSURE CURVE

The auricle and ventricle throughout a large part of the cardiac cycle communicate with one another through the A-V opening, the pressures in the two cavities during this time are therefore practically equal. When auricular and ventricular pressures are recorded simultaneously the two

curves of the curve is inscribed. Upon attaining a value in each ventricle just greater than the aortic or pulmonary diastolic pressure, respectively, the semilunar valves are forced open. This point is marked by line 2 in figure 64. The ventricular cavities and arterial lumina are now in free communication with one another, the ventricular and arterial pressures are practically equal and continue to rise together for a time, but soon reaching their maxima, forms the short plateau or rounded summits of the curves. A sharp decline in the

Fig. 64. Superimposed curves of ventricular, auricular and aortic pressure, together with a ventricular volume curve, an electrocardiogram and a phonocardiogram (see text).

curves run parallel for long stretches (fig. 64). A small positive wave is frequently seen just preceding the main pressure rise of the ventricular curve (line 8). This occurs synchronously with the c wave of the intra-auricular curve and is due to auricular systole. When the ventricle contracts (line 1) the pressure rises rapidly and almost immediately mounts above the auricular pressure. This causes the firm closure of the A-V valves (line 3), as we have seen, actually bulge into the ventricular cavity to produce the c wave. The pressure continues to rise and the steep upstroke

of the curve follows as systole comes to an end and the ventricular muscle commences to relax. The fall in intra-ventricular pressure below the aortic pressure causes the closure of the semilunar valves (line 5). This sharp drop in pressure at the termination of systole produces the incisura of the central arterial pulse (p. 153).

Following the closure of the valves and as a result of the more complete relaxation of the ventricle the pressure curve falls precipitously to finally reach a level below the auricular pressure (line 6). At this instant the A-V valves open and

blood is again received from the upper chamber. Throughout the period which follows in which both auricle and ventricle are relaxed, pressures in the two cavities are approximately equal and at a low level. Toward the latter half of this period, however, the curves may show a gradual rise as a result of the distension of the heart cavities by the accumulated blood and the rise in venous pressure.

THE PHASES OF THE CARDIAC CYCLE AS SHOWN BY THE VENTRICULAR PRESSURE CURVE

The vertical lines numbered from 1 to 8 drawn through the ventricular curve indicate the occurrence of important events in the cardiac cycle. When, as in the figure, arterial, auricular and venous pulse tracings are accurately superimposed with the ventricular curve, that is, when all tracings commence at the same instant and are inscribed beneath one another, then the numbered lines will indicate synchronous events in the various curves at the points of intersection.

The phases of ventricular systole and the post-sphygmic period of ventricular diastole

Ventricular systole is represented by that part of the pressure curve included between lines 1 and 5. That is, from the closure of the A-V valves to the closure of the semilunar valves. In man while the body is at rest, the entire length of ventricular systole is about 0.30 second (from 0.25 to 0.36 second). Its length varies with the pulse rate, shortening with acceleration of the heart, and vice versa. Systole is divided into two periods by the opening of the semilunar valves (line 2). The first of these phases (from line 1 to line 2) is termed the *presphygmic period* or *period of isometric contraction*. The former term implies that this period precedes the appearance of the arterial pulse (sphygmus = pulse); the latter term connotes that the muscle fibers are not shortening. This is actually the case, since the fibers are at this time contracting upon a mass of liquid which is incompressible and completely fills a closed cavity. The second phase (line 2 to line 5) intervenes between the opening and closing of the semilunar valves and is termed the *sphygmic* or *ejection period*, since during this time the blood is being discharged into the aortic and pulmonary arteries. The short period of ventricular diastole immediately following the ejection period and up to the moment of opening of the A-V valves (line 6) is known as the *post-sphygmic period* or *period of isometric relaxation*. During this period the ventricle is again closed and undergoing relaxation, no blood is

entering its cavity so that the length of the fibers remains unchanged—hence the use of the latter term.

In man the presphygmic or isometric contraction period lasts for from 0.04 to 0.06 second. It is subject to little variation under changing conditions of heart rate, etc. The period of ejection takes up the balance of the time of the systolic period, i.e., about 0.25 second. Variations in the length of systole associated with changes in heart rate are brought about chiefly by changes in length of the ejection phase. The latter is prolonged in aortic stenosis.

FIG. 65. Diagram of cardiac cycle. A.S., auricular systole; I.C., period of isometric contraction; M.E., period of maximum ejection; R.F., period of reduced ejection; P., protodiastolic period; I.R., period of isometric relaxation; R.F., period of rapid filling; D., period of diastasis. Divisions of outer circle represent tenths of seconds.

The commencement of the period of isometric contraction is synchronous with the initial vibrations of the first heart sound and follows by a small fraction of a second the beginning of the R wave of the electrocardiogram (p. 181). The termination of this period and the commencement of ejection is marked by the rise in the arterial pressure curve. The end of the ejection period coincides with the beginning of the second heart sound. Therefore, the total duration of systole may be determined in man from the interval elapsing between the initial vibrations of the two heart sounds (p. 175). The time from the commencement of the primary wave in the central arterial pulse (p. 153) to the bottom of the incisura will give the length of the ejection phase, i.e., the time elapsing between the opening and closing of the semilunar valves. The difference between

the time of duration of the whole of systole and that of the ejection phase will give the length of the isometric period. An estimate may also be made of the total length of ventricular systole by measuring the interval from the beginning of R in the electrocardiogram to the end of T.

Wiggers takes as the end of the systolic period not the actual moment of closure of the semilunar valves but the point where the intraventricular

FIG. 67. Henderson's glass cardiometer. H., heart. Arrow is directed towards recording apparatus.

pressure drops suddenly to produce the incisura (p. 153). He further divides the ejection period into two phases. The first of these is termed the period of *maximum ejection* (from line 2 to line 3 in figure 66), which extends from the opening of the semilunar valves to the point of maximal pressure. The somewhat longer second phase during which the pressure is declining gradually and the outflow is lessening is termed the period of *reduced ejection* (line 3 to line 4). The interval elapsing between the end of the latter period and the closure of the semilunar valves, i.e., while the incisura of the central arterial pulse is being inscribed (line 4 to line 5), is included by Wiggers in the diastolic period and termed the *protodiastolic phase*. In the dog's heart the total duration of systole as thus defined was found to be from 0.15 to 0.26 second. The periods of maximum and reduced ejection were 0.05 to 0.12 and 0.06 to 0.14 second respectively.

The phases of ventricular diastole

The postsphygmie period or period of isometric relaxation and the protodiastolic phase of Wiggers have already been mentioned. After the opening of the A-V valves (at the end of the period of isometric relaxation) the blood flows rapidly into the ventricle; the intraventricular pressure curve falls to the zero line (line 6 to line 7 fig. 64). This is spoken of as the period of *rapid filling*. Unless the heart is beating rapidly the period of rapid filling is followed by one during which the ventricle, being already nearly full, fills more slowly. During this period (line 7 to line 8) the ventricular volume increases very little; the intraventricular pressure may rise slightly. The term *diastasis* has been given to this phase by Henderson. Auricular systole follows the period of diastasis and, as already seen, causes the small pressure wave in the ventricular curve at the end of the diastolic period. It has been pointed out (p. 170) that only the first half of auricular systole is responsible for this pressure rise. The period of diastasis is much curtailed or abolished when the heart beats rapidly, in which event auricular systole may ensue at the end of the phase of rapid filling, or after only a brief period of diastasis. The period of diastasis lengthens of course as the heart rate slows. The phases of the cardiac cycle are shown diagrammatically in figures 65 and 66.

Duration of different phases of diastole in the human heart

Diastolic phases:	Total duration	seconds
		averages
	0.50	
Protodiastolic period (Wiggers).....	0.04	
Isometric relaxation (post-sphygmie).....	0.08	
Rapid inflow.....	0.09	
Diastasis	0.19	
Auricular systole	0.10	

The volume curve of the ventricle

By enclosing the ventricles in a chamber as shown in figure 67 and connecting the cavity of the chamber to a recording apparatus the changes in volume of the heart during the cardiac cycle may be studied. Such an instrument is called a *cardiometer*. The curve so obtained is of course quite different from the intraventricular pressure curve (see fig. 64).

CHAPTER XXII

THE MOVEMENTS OF THE HEART VALVES. THE HEART SOUNDS

The chief factor concerned in the opening and closing of the valves is, as already indicated (p. 171) the difference in pressure upon their opposite surfaces. Some additional features of the valvular mechanisms must now be considered.

THE AURICULO-VENTRICULAR VALVES (TRICUSPID AND MITRAL)

The valve leaflets or cusps, three in number on the right and two on the left side, are attached by their bases to the fibrous rings surrounding the auriculo-ventricular openings. Their free margins are connected through delicate tendons (chordae tendineae) to the papillary muscles which prevent inversion of the valves into the auricle during ventricular systole. The chordae tendineae are tightened at the commencement of systole by the contraction of the papillary muscles. The leaflets are composed mainly of a double layer of the endothelial lining of the heart, strengthened by a few connective tissue fibers. Their attached bases are thicker and contain more connective tissue, small blood vessels and delicate strands of smooth muscle. The latter, however, play no part in valve closure which is effected, as mentioned above in a passive manner.

The mechanism of valve closure

During auricular systole the leaflets do not lie back against the ventricular wall, but occupy a mid-position as a result of two opposing currents. The inflowing blood pressing upon their auricular surfaces keeps them open, while eddies reflected in the reverse direction from the ventricular walls strike their ventricular surfaces and tend to close them. Thus they float in a position of delicate balance. When, as a result of the fall in intra-auricular pressure as auricular systole terminates, the incoming jet is diminished in force and finally ceases, the back eddies persisting for a brief space and being unopposed, approximate the valves or bring them gently into apposition (fig. 68). They are not, however, firmly closed. This is effected by the rise in pressure in the ventricle when it contracts. Dean has shown by attaching a hair to the septal leaf of the valve and recording its movements, that if ventricular systole does not

follow almost instantly upon the cessation of the flow of blood from the auricle the valves start to reopen. In instances, therefore, in which ventricular systole is delayed, that is, when the A-V interval is prolonged, the reopening of the valves proceeds for an appreciable time. Then, when ventricular contraction occurs a small amount of blood regurgitates into the auricle before the valves are swung closed by the rising intraventricular pressure. The backward flow of blood through the orifice may then give rise to a murmur just preceding the first heart sound (presystolic murmur).

FIG. 68. Two diagrams showing mechanisms concerned in valve closure. A, showing relations of papillary muscles and chordae tendineae to valve flaps; B, partial closure due to eddy formation (after Wiggers).

THE SEMILUNAR VALVES

The dynamics of aortic and pulmonary closure are essentially the same in principle as those described for the A-V valves. The valves form three small pockets open toward the arterial lumen. Back eddies which are set up during the ejection phase of systole prevent the contact of the valves with the arterial wall. When ejection ceases the centripetal currents carry the valves into apposition and firm closure is effected by the higher pressure upon their arterial surfaces at this time.

THE HEART SOUNDS

Two sounds can be heard during the cardiac cycle. The *first sound* is of relatively long duration, soft in quality and low in pitch. The *second sound* is shorter, sharper and of higher pitch.

These characteristics are best imitated vocally by the syllables "lub" and "dup" separated by a brief pause. The two heart sounds mark the beginning and end of ventricular systole and the determination of the interval between their commencements (as determined by the phonocardiogram) is the most reliable method for arriving at the length of ventricular systole in man. The pause between the end of the second sound and the beginning of the first coincides with ventricular diastole.

The factors concerned in the production of the sounds

THE FIRST SOUND is heard most clearly and at maximal intensity by placing a stethoscope over the fifth left intercostal space ("apex beat"). It is generally taught that two factors, at least, enter into the production of the first sound, (1) contraction of the ventricular muscle and (2) the closure of the A-V valves and the vibration set up by the tension of the valve leaflets and chordae tendineae as the intraventricular pressure rises.

The contribution which other events make to the production of the first heart sound, e.g., the opening of the pulmonary and aortic valves, the rush of blood from the ventricles and the shock transmitted to the walls of the pulmonary artery and aorta, have been the subject of much debate but there is no general agreement. Some deny that the sound is prolonged into the period of ejection and, therefore, would exclude these factors from participation in its production. The observations of Straub and of Orias and Braun-Menendez indicate that the sound is prolonged beyond the isometric period, and it is probable that some, if not all, of the factors mentioned play a part, if only a minor one, in producing it. There is no doubt that the vibrations set up in the leaflets of the auricular-ventricular valves as they are put under tension at the beginning of ventricular systole, constitute an important factor in the production of this sound. The existence of a muscular element, however, has been questioned. Dock recorded the sound vibrations by means of a phonocardiograph applied to the surface of the heart and reported that no sound was produced when the empty heart contracted, valve action being abolished. Although he concluded from this that the normal first sound contained no muscular element, evidence from other sources is strongly opposed to such a conception. Wiggers and Dean, previously, had recorded sound vibrations from an isolated strip of myocardium. It has also been shown that when free movement of the

valves of the beating heart is prevented, the booming character of the first sound still persists.

Phonocardiographic records from the chest over the heart show no vibrations before the onset of ventricular contraction (fig. 64) thus indicating that the presystolic apposition of the valves is silent. The sound commences 0.008 second before the peak of the R wave of the electrocardiogram. Its duration is about 0.18 second.

THE SECOND SOUND results from the vibrations set up in the blood column and arterial walls, as the aortic and pulmonary valves are placed under tension following their closure. The duration of the second sound is about 0.10 second. It commences about 0.09 second after the summit of the T wave of the electrocardiogram. It is heard best over the pulmonary and aortic areas—the upper part of the sternum adjacent to the second left intercostal space, and the second right costosternal junction, respectively.

THE THIRD HEART SOUND. Sometimes a faint third sound is heard in normal hearts which follows the second sound by about 0.08 second and lasts for about 0.04 second. It is heard at the apex and is commonly found in young adults. Thayer found it present in 65 per cent of normal individuals. It may be made to appear or is intensified by procedures which increase the venous flow into the auricles, e.g., exercise, recumbent position, etc. The sound was first described by Gibson and independently by Herschfelder; several explanations have since been given to account for it. (1) Some have considered it to be due to the asynchronous closure of the aortic and semilunar valves, but the interval between it and the second sound is too great for the acceptance of this explanation. (2) White considers that it is due most probably to the opening snap of the A-V valves or to the vibration of the ventricular walls as the blood rushes into the ventricle. (3) Another view is that the sound is simply due to prolonged after vibrations of the aortic valves which have become separated from the earlier vibrations as a silent interval. None of these explanations is entirely satisfactory in all instances.

Variations in the intensity of the heart sounds

It is the general belief that the first sound varies in intensity with the force of ventricular systole and the loudness of the second sound with the height of the arterial blood pressure. The experiments of Wiggers bear this out. The sounds were recorded graphically and correlated with the intraventricular and aortic pressure curves. It was found that the vibrations of the first sound were increased in amplitude and number when the

tension developed by the cardiac muscle was increased. The intensity of the first sound is directly related to the rate of the pressure rise within the ventricle during the isometric period. The intensity of this sound is not dependent upon the volume of the systolic discharge but rather upon the diastolic pressures in the pulmonary and systemic circuits. Wiggers found that when the heart was slowed and the systolic discharge consequently increased but the diastolic pressure lowered, the intensity of the first heart sound was reduced while acceleration of the heart (reduced

FIG. 69. *S*, stethoscope bell; *O*, side tube to air; *M*, microphone; *C.Z.*, dry cell; *R*, resistance; *K¹*, key in galvanometer circuit; *T*, induction coil; *K²*, key in microphone circuit; *G*, galvanometer (after Lewis).

systolic discharge with raised diastolic pressure) increased its intensity.

The intensity of the second sound in the aortic or pulmonary area is increased by an elevation in the systemic or pulmonary pressures, respectively. Among the cardiovascular conditions associated with intensification of the second sound are, mitral stenosis and failure of the left ventricle which raise the pulmonary arterial pressure, and arterial hypertension which raises the aortic pressure.

THE GRAPHIC REGISTRATION OF THE HEART SOUNDS.
The phonocardiogram. The instrument employed for this purpose consists of a stethoscope fastened to the

chest and provided with a side-tube open to the air so as to obviate pressure changes, a microphone and a string galvanometer (fig. 69). A type of apparatus devised more recently (Kauntz and associates) avoids the acoustic errors of air transmission and employs a water-filled capsule in contact with the chest. The vibrations are picked up by a dynamic type of microphone. The electrical currents are transmitted to an amplifier and thence to the vertical plates of two cathode tubes. The vibrations are recorded photographically.

The record of the first sound is composed chiefly of a series of from 7 to 13 vibrations. These are of small amplitude to start with but rise to a "crescendo" which reaches its maximum at the end of the isometric period and is followed by a "diminuendo" of about the same duration. This main series of vibrations is preceded by a couple of small introductory vibrations which occur prior to the ventricular pressure rise. These are possibly of auricular origin. The main series is also followed by a few final vibrations, variable in number. The vibrations are in general irregular, which places the sounds in the category of noises rather than of musical tones. The frequency is low, being on the average 45, 50, and 33 per second, respectively, for the first, second and third sounds. A normal and a series of abnormal phonocardiograms are shown in figure 70, page 178.

Graphic registration of the heart sounds has permitted precise relationships to be established between them and the events of the cardiac cycle, as recorded by other graphic methods, e.g., intracardiac pressure curves and the electrocardiogram. The phonocardiogram also, as already mentioned, provides an accurate method of measuring the length of ventricular systole.

ABNORMAL HEART SOUNDS

Murmurs

When the valves at one or other of the cardiac orifices become deformed by disease, they impede the flow of blood or allow leakage to occur, and abnormal sounds replace either partially or completely the usual heart sounds. Such sounds are spoken of as murmurs or bruits. When the valves produce narrowing of one of the orifices of the heart, the condition is spoken of as *stenosis*; thus *aortic* or *mitral stenosis* implies restriction of the respective opening and increased resistance to the flow of blood through it. The velocity of the blood flow through the constricted orifice is also increased. The valve surfaces are usually roughened and the smoothly rounded and somewhat funnel-shaped nature of the opening is lost. All these factors contribute toward the abnormal sound. When the valves are incapable of closing tightly they are said to be *incompetent*. They no longer perform their duty but allow blood to pass through

the orifice in a direction the reverse of that of the circulation. So *aortic* or *mitral incompetence* or *regurgitation* is spoken of to indicate leakage of the respective valve. Obviously if the valves are deformed sufficiently to produce narrowing of a particular orifice, they will also be incapable of closing properly and leakage will occur as well.

of blood at this time. At the end of the period of ejection they should close tightly. If however the orifice is stenosed, the obstruction causes a murmur to be heard during ventricular systole which replaces or modifies the clear first sound. This is referred to as a *systolic murmur*. If, on the other hand, the valves are incompetent and do not come together at the end of the

FIG. 70. A, normal heart sounds recorded from apex; B, a diastolic murmur of aortic origin; C, presystolic murmur; D, gallop rhythm, presystolic (1') type; E, gallop rhythm, early diastolic (2') type. The numbers 1 and 2 refer to the heart sounds; M, murmur (after Lewis).

Stenosis is therefore usually associated with a certain degree of incompetence.

TIME RELATIONS. The particular valve involved is determined from the relation of the murmur to the events of the cardiac cycle and from the point upon the chest wall where the sound is transmitted with the greatest intensity. For instance, the aortic valves should be open during the ejection phase of ventricular systole so as to offer little or no resistance to the outflow

systolic discharge, a rush of blood from the aorta into the ventricle occurs in diastole, and a murmur modifies the normal second sound—*diastolic murmur* (fig. 70 B). The murmur may appear in early, mid-, or late diastole or may persist throughout almost the entire period. When stenosis and incompetence co-exist a murmur may be produced at the aortic orifice during both systole and diastole, in which event the two normal sounds are replaced by a to and fro blowing sound. A systolic murmur will also be caused by incompetence of the

A-V valves (tricuspid or mitral) since the rise in pressure during ventricular systole will drive blood backwards into the auricle and cause abnormal vibrations to be set up.

Mitral stenosis (stenosis of the tricuspid orifice is very rare) by offering an obstruction to the flow of blood from the auricle into the ventricle may cause a murmur to be heard at any time between the second and the first heart sounds. The intensity, duration and timing of the sound vary with the degree of stenosis and the rate of blood flow through the orifice. Though the murmur may extend throughout diastole it tends to be more intense toward the beginning and the end of diastole; it may be heard only during these times, or be confined to one or other of them. As pointed out by Lewis, the rate of blood flow into the ventricle which is an important factor in the production of the abnormal sound, is most rapid during these phases of diastole. At the end of diastole an impetus is given to the blood by the systole of the auricle; while the early part of diastole is the period of rapid filling (p. 173) of the ventricle. The late diastolic murmur (presystolic) may therefore disappear when auricular fibrillation supervenes and abolishes the propulsive action of auricular systole. When the heart is beating slowly the murmur is more likely to be well marked in early and in late diastole. The blood which has accumulated in the auricle during the preceding ventricular systole rushes through the mitral orifice when the valves open, but the flow slows as the ventricle becomes full (period of diastasis), so the murmur disappears. It reappears again when the auricle, distended with blood as a result of the prolongation of diastole, contracts. When the beat is rapid and the period of diastasis abolished, the murmur is likely to be heard throughout diastole which is then occupied entirely by the phase of rapid filling. Aortic regurgitation is not uncommonly associated with a presystolic murmur. Such as described many years ago by Austin Flint and is usually referred to as the *Flint murmur*. According to the most generally accepted explanation, it is due to vibrations set up in the anterior leaflet of the mitral valve which is pushed by blood regurgitating through the aortic orifice into the path of the stream entering from the auricle. Gouley has described a characteristic deformity of the right leaflet of the aortic

valve which he declares served to direct the regurgitating blood against the mitral leaflet.

GALLOP OR CANTER RHYTHMS. In certain cardiac conditions three distinct sounds are heard which give rise to a rhythm not unlike the gallop or canter of a horse. In some cases the abnormal sound precedes the first sound—the *presystolic type* of gallop rhythm. Two sounds are heard in rapid succession followed by a pause, and then by the second sound (fig. 70, D). This type is associated with depressed auriculo-ventricular conduction (p. 190) or sometimes with bundle branch block (p. 192). The extra sound is attributed to the forceful contraction of the auricle. Ordinarily the ventricular contraction follows so closely upon auricular systole that any sound set up by the contraction of the auricle merges with the first sound. But when, as a result of slowed conduction in the A-V bundle, the auricular and ventricular systoles are separated by an appreciable interval the contraction of the auricular muscle may become audible. The engorgement of the auricle, due to the delay in the ventricular contraction and the hypertrophy of the auricular muscle which frequently exists, also favor the production of the sound.

In other cases the abnormal sound follows shortly upon the second heart sound—*early diastolic type* of gallop rhythm (fig. 70, E). In some instances the extra sound is simply an intensification of the third sound described above as occurring in normal subjects. It may then, though very occasionally, follow strenuous muscular exercise. In most instances this type of gallop rhythm is associated with cardiac failure and is then indicative, usually, of a severe myocardial damage. The abnormal sound is not caused by asynchronous closure of the pulmonary and aortic valves. It is most probably due to vibrations set up in the walls of the dilated ventricle caused by the shock of blood as it rushes from the auricle under a high head of pressure. The sound therefore follows upon the opening of the A-V valves, i.e., after the period of isometric relaxation (p. 173).

When the heart rate is slow and auriculo-ventricular conduction much prolonged, a type of gallop rhythm may develop in which the abnormal sound occurs near the middle of diastole—*mid-diastolic type* of gallop rhythm—and is attributed to a forceful contraction of the auricle.

CHAPTER XXIII

ELECTROCARDIOGRAPHY. THE VENOUS PULSE

GENERAL DESCRIPTION OF THE ELECTROCARDIOGRAPH

The electrocardiograph as devised by Einthoven is, in essence, a very sensitive galvanometer. The cardiac action current is led through a fiber of finely spun silver-coated quartz glass, 0.002 mm. in diameter (about $\frac{1}{4}$ of the diameter of a red cell). The fiber, or "string" as it is termed, is suspended vertically in a holder between the poles of an electromagnet. When the magnet is excited by a powerful current an electric field is set up, the lines of force passing from its north to its south pole. The heart current is conducted through the string (fig. 71). A strong beam of light is directed through apertures in the arms of the magnet lying in front of and behind the string. The latter and its lateral movements (deflections) are thus cast as shadows which are magnified and brought to a focus upon a moving photographic surface (plate, film or sensitive paper) moving vertically at the desired speed in a camera of special design.

The sensitivity of the string is standardized so that a deflection of 1 centimeter represents 1 millivolt. Horizontal lines a millimeter apart are marked on the record by means of etchings upon the camera lens. Each division represents $\frac{1}{10}$ millivolt. The shadows thus cast upon the photographic surface are registered as the deflections or waves in the electrocardiogram mentioned above and described in detail on page 181.

The passage of the heart current causes circular lines of force to be set up around the fiber. These take a clockwise or anti-clockwise direction according to the direction (descending or ascending) taken by the cardiac current, and cause the string to move, respectively, inwards toward the arch of the magnet or outwards. Time is indicated by vertical lines caused by some form of timing device which breaks the beam of light at regular intervals. The finer vertical lines indicate $\frac{1}{8}$ second, heavier ones $\frac{1}{4}$ second.

The string galvanometer type of electrocardiograph is the one in most general use today but within recent years an instrument employing a moving magnet or moving coil galvanometer and radio tube amplification has been devised.

THE ELECTROCARDIOGRAPH LEADS

We have already seen (p. 165) that the electromotive force developed in the cardiac muscle of an

experimental animal can be recorded by placing paired contacts directly upon the surface of the heart and connecting them with a galvanometer or by placing one contact upon the heart and the other upon some indifferent part of the body. Records obtained in this way are called *electrograms*. It is clear that the electrical changes occurring immediately beneath a contact electrode will dominate the record. The heart *in situ* is, however, surrounded by a conducting medium—the blood and tissue fluids which are, in fact, solutions of electrolytes. It is possible, therefore, to connect the electric field set up about the heart during its beat by leading off from certain paired regions upon the body surface to the string of the electrocardiograph. A part of the electromotive force developed by the heart can in this way be "tapped" and the activity of any part of the cardiac muscle, and not merely the region beneath the electrodes as in the case of electrograms, will impress its influence upon the electrocardiogram. The parts of the body employed for this purpose are the two forearms (or hands) and the left leg (or foot). These may be coupled in any one of three combinations, each of which is referred to as a *lead*. Thus the three standard leads are—

Right arm and left arm = *lead I*

Right arm and left leg = *lead II*

Left arm and left leg = *lead III*

Flat pliable metal electrodes (3" x 2" in area) covered with gauze soaked in strong salt solution or with a jelly composed of salt, tragacanth, glycerine and water are applied to the forearms and the left leg above the ankle. By means of a switch on the control board of the electrocardiograph, a record from each lead can be taken in turn.

A fourth or precordial lead is now frequently used in addition to the three standard leads and is generally recommended as a routine procedure. Wolferth and Wood showed that if only the three standard leads were used, important electrocardiographic changes occurring in the antero-posterior diameter may be missed. For recording the precordial lead, one electrode is placed upon the fourth intercostal space to the left of the sternum, the other on the posterior wall of the chest directly opposite the first. The anterior electrode is attached to the right hand terminal of the control box and the posterior electrode to

the terminal for the left hand. The P wave in lead IV is frequently inverted or notched and may be diphasic. The P-R interval is longer by from 0.01 to 0.03 second than in lead II. The R wave is, as a rule, higher (20 mm. or more) than in the standard leads, the Q wave is very pronounced and the S wave absent. The T wave is usually inverted.

THE NORMAL ELECTROCARDIOGRAM

During the cardiac cycle the electrical changes in the heart cause five distinct movements or deflections of the galvanometer string. Three of these are directed inward, i.e., toward the arch of the magnet; two are directed outward. The photographic surface, as we have seen, moves

FIG. 71. C, C, galvanometer string; N and S, north and south poles of electromagnet. Further description in text.

perpendicularly from above downward. The movements are, in consequence, marked in the record as deflections to one or other side of a vertical zero line representing the isoelectric position of the string. The electrocardiogram, however, is always examined after rotating the plate to the left into the horizontal position, when the deflections appear as waves above or below the zero line. The waves from left to right have been designated simply by the letters of the alphabet, P, Q, R, S and T (fig. 72). P, R and T are directed upward, Q and S downward. Q is not always present. A fourth small positive wave, U, is sometimes seen in leads I and II immediately following T. Its significance is unknown. The ventricular lines in this figure mark fifths of seconds; the horizontal lines, 1 mm. apart, indicate tenths of millivolts.

The P wave is produced by the spread of the excitation wave over the auricles. Notching of the P wave not infrequently occurs in leads II and III, and occasionally in lead I. The duration of the P deflection as measured along the base line averages 0.08 second. It precedes the auricular contraction by about 0.02 second.

The Q, R, S and T deflections are produced by the ventricles, the first three waves during the spread, and the T wave during the retreat of the excitation wave (p. 187). The duration of the QRS complex varies inversely with the heart rate (usually from 0.04 to 0.08 second). A duration exceeding a tenth of a second is abnormal.

The R wave commences about 0.02 second before the beginning of the rise in the intraventricular pressure curve (p. 171); it reaches the base line again before the semilunar valves open.

The duration of the P-R interval (from the beginning of P to the beginning of QRS) varies inversely with the heart rate; the normal range being from 0.15 to 0.20 second in lead II. It is somewhat shorter in the other standard leads and longest in lead IV. The length of the interval is taken as an index of the conduction time over the auriculo-ventricular connections. A value exceeding the upper normal limit of a fifth of a second (with heart rate of 70 or over) indicates an abnormally slow conduction rate (p. 190).

The S-T interval, that is, the interval elapsing between the end of the S wave and the commencement of T during which the record closely follows the base line, varies in length from 0.10 to 0.25 second according to the rate of the heart. It coincides approximately with the period of maximum ejection of ventricular systole (p. 172). The end of the T wave corresponds in time with the beginning of the period of isometric relaxation, i.e., to the closure of the semilunar valves. A measurement of the Q-T interval (beginning of Q to end of T) gives the length of ventricular systole. The Q-E interval, i.e., the lapse of time between the commencement of the Q wave and the commencement of ventricular ejection as determined from the subclavian pulse, is from 0.10 to 0.16 second.

Voltages. The highest wave of the electrocardiogram (R wave) in lead II varies in amplitude among normal subjects from 7 to 18 mm. (i.e., potential values of from 0.70 to 1.80 millivolts). The relative heights of the other deflections may be seen in figure 72.

THEORY OF ELECTROCARDIOGRAPHIC INTERPRETATION

EINTHOVEN'S TRIANGLE

First let a geometrical proposition be considered. Let an equilateral triangle, ABC, be described and a straight line, DE, be drawn in any direction within it,

FIG. 72. Normal electrocardiogram (kindness of Dr. John Hepburn).

and let this line be projected perpendicularly on to the three sides (P_1 , P_2 and P_3 , fig. 73, I). Then the longest projection (which in the illustration is P_1) equals the sum of the other two (i.e., P_1 and P_2 in the instance depicted. This is true no matter what may be the direction of DE.

Next let a plate of conducting material be fashioned in the form of an equilateral triangle (fig. 73, II) and let any two apices of the triangle be connected through a galvanometer so that when the fall in potential is from A to C either through B or directly to C the galvanometer deflection is upward, i.e., positive, and when the fall in potential is in the opposite direction, the deflection is downward or negative. When an electromotive force, whose magnitude and direction are represented by one or other of the two central arrows shown in the figure, is developed within the triangle, then the potential difference between any two of the latter's apices will be proportional to the length of the projection of the arrow upon the side connecting these apices. The length of the projection on a given side of the triangle, and so the recorded potential change which it represents, will vary, of course, with the angle which the arrow makes with that side. Whether the central EMF produces an upward or a downward deflection will de-

FIG. 73. Description in text. Vertical lines mark $\frac{1}{2}$ sec.

and upon its general direction. In the figure all the projections of the solid arrow are positive; two of the projections of the arrow drawn in interrupted lines are negative and one positive. But the arrow might point in any direction, and depending upon its direction in relation to a given side of the triangle its projection upon that side will be of positive or of negative sign. It will be found, nevertheless, that in whatever direction the arrow points, the *algebraic* sum of its projections on the sides AB and BC will equal its projection on AC. Finally, let the three electrocardiographic leads be imagined as forming an equilateral triangle about the heart (fig. 73, III); let the electrical axis of the heart (p. 184) be represented by the arrow, and the potential differences, negative or positive, which are recorded (as deflections) in the electrocardiogram in the three leads, be taken to correspond to the projections of the arrow upon the respective sides of the triangle. Then the potential difference between any two points upon the body represented by the apices of the triangle will vary in magnitude according to the angle which the arrow makes with the lead joining these points, and be proportional to the projection of the arrow upon the line of the lead. So the *algebraic sum of the potential differences as recorded in leads I and III will equal that recorded in lead II*. This truth, first enunciated by Einthoven, is expressed by the following formula, $e^1 + e^3 = e^2$, in which e represents potential difference and the numerals the respective leads. It forms the basis for the interpretation of the electrocardiogram. It is a remarkable fact that such a mathematical formula, though empirical as applied to electrocardiography, is in such close agreement with the actual facts derived from experiment.

THEORY OF LIMITED POTENTIAL DIFFERENCES

It has been supposed that the excitation wave travelled through ventricular muscle from the base (region of A-V ring) to the apex of the heart and then from apex to base, and so followed a course laid down by the doubling upon itself of the embryonic cardiac tube (notch). The excitation wave commencing at the base caused, it was supposed, this region to become negative to the apex, and so produced a deflection upon the line of the tracing, i.e., the R wave. The wave on moment later having reached the apex caused this to become relatively negative, the current was reversed and a deflection—the S wave—was inscribed below the zero line. The return of the wave to the base in the region of the great vessels and its final retreat from this part is believed to cause the T wave.

But this simple explanation is no longer satisfactory. The excitation wave does not spread through the ventricular muscle in this manner. As we have seen, the wave follows a more or less semicircular course around the interior of each ventricle along the branches of the bundle and the Purkinje network. The rate of travel is very rapid, the wave taking only about 0.04 second to complete its journey. Also, it moves in a different

direction in each ventricle—clockwise in the right, and anti-clockwise in the left—exciting in its passage the overlying muscle (fig. 75). Thus regions quite local in nature and perhaps within a single muscle fiber itself are created, which are relatively negative to the unexcited tissue which immediately adjoins and precedes them. So are visualized paired electrical charges of opposite sign but of equal value. These, which may be likened to minute batteries each with its positive (active tissue) and negative (inactive tissue) poles, are referred to by Craib as *electrical doublets*. The rest of the heart is electrically neutral at the moment and not concerned with the development of potential differences. As the excitation process spreads through the Purkinje

FIG. 74. Illustrating the evidence provided by an experiment of Lewis' for the theory of limited potential differences, see text (after Lewis).

system, muscle fibers in each ventricle become successively involved with the production of innumerable action currents which flow outward through the muscle.

The heart muscle then must be looked upon electrically, not as a whole, i.e., a mass of muscle over which the electrical change spreads in a regular manner from base to apex and subsequently from apex to base, but rather as consisting of innumerable units in which action currents having different directions at any given instant and from one instant to the next, are developed. Some of these will neutralize, others will reinforce, one another. It is the algebraic sum of these potential changes which determines the potential differences as recorded by the electrocardiograph. The resultant of the electromotive forces developed within the heart at any instant will have a certain definite direction which is spoken of as the *electrical axis of the heart*. It is the direction of current flow, i.e., of the electrical axis rather

than the location relative to one another of two oppositely charged masses of cardiac muscle, which determines the characters of the electrocardiogram. The foregoing view of the electrical changes is known as the theory of *limited potential differences*. The theory of *distributed potential differences*, as the base to apex view is termed, has been shown inapplicable by the following experiment of Lewis.

In figure 74, I is represented a heart immersed in saline. The electrodes Z and C are connected through a galvanometer. If, as shown in figure 74, II, the epicardial surface be stimulated at 2, a region of negativity is created, the electrode Z becomes negative to electrode C, and a current flows as indicated by the arrow. The duration of flow might be explained by either theory, for it is seen that whether the tissue Z is relatively negative to the rest of the entire ventricular muscle, as the theory of distributed potential differences demands, or is negative only to a region immediately adjoining itself, the current's direction will be the same. If, however, the endocardial surface is stimulated at 1, fig. 74, III), then the current first flows in the opposite direction; Z is positive and C negative. This is incompatible with the older theory since, if the point of stimulation is relatively negative to all unexcited regions of the heart, the current should be in the same direction as when the epicardial surface was stimulated. It has also been shown that the S wave is actually produced by the spread of the excitation wave to the region of the base, and not by the development of negativity at the apex, which alone could satisfy the base to apex theory. Furthermore, in the cold-blooded heart the base is not always activated before the apex, yet an upright R wave is found in any event.

THE ELECTRICAL AXIS OF THE HEART

Determination of the electrical axis

The graphic method of Fahr may be employed. In order to determine the direction for the electrical axis records are taken in leads I and II. The amplitude of the electrocardiogram at synchronous points (e.g., the R waves) in each record is measured in millimeters (1 mm. = $\frac{1}{10}$ millivolt) and the distances laid off upon the corresponding sides of the triangle (fig. 73, IV) commencing from the angle A. Perpendiculars are dropped from the ends of these measurements (C and D) toward the center of the triangle until they intersect at B. A line joining A and B gives the direction of the electrical axis at the moment that the particular deflections were inscribed. The full potential difference developed in the heart can never be known. The *manifest* value is the maximal potential difference which can be recorded, i.e., when the electrical axis lies parallel to the lead (see below). The length of AB in millimeters gives the manifest value in tenths of millivolts.

It should be pointed out that, though the electrical changes are occurring in all planes of the heart muscle, the electrocardiogram registers those in one plane only,

just as a roentgenogram depicts the heart in two and not three dimensions.

The rotation of the electrical axis

Determinations of the electrical axis at successive moments throughout the cardiac cycle have shown that its direction is continually changing. This follows naturally from the fact that the electrical axis is an expression of the balance that has been struck at the moment between separate action currents. Since the directions of these vary from instant to instant, the direction of the resultant force would be expected to vary likewise (fig. 75). During the spread of the excitation wave in the heart the electrical axis swings in an orderly manner from left to right.

The magnitude of the potential difference existing at any instant between the two electrodes of any lead depends upon the angle which the electrical axis makes with the line of that lead. This is simply expressing in another way what has been said elsewhere, that the potential difference recorded in any lead is proportional to the length of the projection of the line representing the electrical axis on to the side of the triangle corresponding to that lead. Consequently, when the electrical axis is perpendicular to the lead no potential difference is developed in that lead and the electrocardiogram, so long as the axis bears this relationship, follows the isopotential line. When the axis forms an angle greater or less than 90° with the lead, a difference of potential will be developed between its electrodes; when the axis lies parallel to a lead the maximal potential (manifest value) is established and the maximal deflection of the string occurs. Potential differences having values intermediate between zero and the maximum will be developed when the axis is other than parallel or perpendicular to the line of the lead. The magnitude of the differences will be greater or less according to the degree to which the axis swings toward one or other of these positions.

Depending upon the direction of the axis in relation to the line of the lead, the deflection may be either positive or negative. For example, if the axis is in the general direction of the small arrows shown on the sides of the lowest triangle in fig. 73, i.e., from RA to LA in the case of lead I, from RA to LL in lead II and from LA to LL in lead III, then the deflection in the respective lead will be above the base line. If the axis swings beyond the right-angle position so as to point in a reverse direction in one or other lead, then the deflection is negative in that lead.

THE COMPOSITE NATURE OF THE PHYSIOLOGICAL ELECTROCARDIOGRAM

The researches of Lewis have demonstrated that the normal electrocardiogram is in reality a record of dual effects fused together. That is, deflections are produced by electrical changes in each ventricle separately, and these become

ended together are written as the characteristic series of waves in the normal tracing. Though the excitation wave reaches both ventricles simultaneously, it spreads independently in each chamber via the corresponding bundle branch and Purkinje system (fig. 75). The direction of spread is opposite in each half of the heart, being clockwise in the right chamber and anti-clockwise in the left. If, therefore, the electrical changes could be recorded in each ventricle separately and the resultant of the action currents, i.e., the electrical axis of each ventricle, be determined, it might be expected that the axis would swing from left to right on the right side and from right to left on the left. This was found to be the case. Such experiments have shown that the electrical axis

FIG. 75. A diagram of the human heart in section, presenting the directions in which the excitation wave spreads in the human ventricle and the time in seconds at which, after its commencement in the ventricle, the wave first reaches various regions of the ventricle. (After Lewis.)

of the whole heart is the resultant of the electrical axes of the two ventricles. Lewis divided (or compressed) one or other main branch of the bundle in dogs and in monkeys. When one branch of the auriculo-ventricular bundle is severed, the spread of the excitation wave to the corresponding ventricle is delayed, the electrical changes of the uninjured ventricle commence first and are consequently unbalanced by those of the opposite chamber. The QRS complex then depicts the electrical changes of the uninjured ventricle alone. When the excitation wave reaches the disabled chamber later by the only path open to it, namely, through the septum from the uninjured side and at the relatively slow conduction rate characteristic of the cardiac muscle. Lewis obtained records of the uninjured ventricle after division of the bundle of the opposite side and termed the unilateral

tracing obtained in this way a *dextrocardiogram* or a *levocardiogram* according to whether the QRS deflections represented the electrical changes in the right or left ventricle, respectively. The former was, of course, produced by left, the latter by right bundle branch injury (see fig. 77). The canine dextrocardiogram has the following characteristics. In lead I the R wave is reduced and the S wave is increased. In the levocardiogram these characteristics of the two leads are interchanged. Lead I of the levocardiogram resembles lead III of the dextrocardiogram, i.e., the chief deflection is upward. Lead III of the levocardiogram resembles lead I of the dextrocardiogram, namely, the chief deflection is downward. Extrasystoles produced by stimulation of the right or left ventricle in dogs gave records having the general features of a dextrocardiogram or of a levocardiogram, respectively (see also p. 192).

When the QRS complexes of the two sides of the heart are plotted separately on a large scale and with identical time relations (as shown for the left side in fig. 76) then a third curve can be constructed by the algebraic summation of the values in the former two. This calculated curve, termed the *bicardiogram*, presents the characteristics of the normal electrocardiogram.

DEVIATION OF THE ELECTRICAL AXIS

The direction of the electrical axis, of course, bears a relationship to the anatomical axis of the heart. The latter may be taken as passing longitudinally through the interventricular septum, being directed forward, downward and to the left and roughly parallel to the side of the triangle represented by lead II. Obviously, changes in the position of the heart in relation to the sides of the triangle enclosing it will, by causing corresponding alterations in the direction of the electrical axis, be reflected in the electrocardiogram. The heart alters its position slightly during ordinary respiration. During expiration, as a result of the ascent of the diaphragm, the apex swings upward and to the left, i.e., anti-clockwise, and the heart assumes a more transverse position; the opposite movement occurs during inspiration. Even changes in the position of the body (turning in bed from one side to the other) or distension of the stomach may cause slight changes in the direction of the anatomical axis. A rotation of the heart to the left tends to alter the direction of the electrical axis (*left axis deviation*) in such a way as to increase the amplitude of the R wave and reduce the S wave in lead I, and to reduce the

FIG. 76. (Slightly modified from Lewis.) Levocardiogram obtained from a dog after division of the right branch of the auriculo-ventricular bundle. Lower figure shows the directions of the electrical axis in the left ventricle during the initial phases (QRS) of the electrocardiogram, calculated at intervals of 0.005 second. The triangle represents the three leads. The axis rotates in a regular anti-clockwise direction. In the chart above, the potential values recorded in the three leads are plotted at corresponding time intervals. It will be noted that the angle which the electrical axis makes at any instant with a given lead determines the sign and magnitude of the potential difference in that lead. (Ordinates, 1 cm. = 1 millivolt; abscissae, 1 cm. = 0.02 second.)

R wave and increase the S wave in lead III. The more transverse position of the heart tends also to reduce the P and T waves in lead III or to cause inversion of the T wave. Movement of the heart into a more vertical position produces the opposite effects (*right axis deviation*) upon the QRS complex—reduction in the height of the R wave in lead I with an increased depth of the S wave, a small P and an upright T. In lead III the amplitude of R is increased. Thus, in left axis deviation, the electrocardiogram has the characteristics of the so-called levocardiogram, described on page 185, and right axis deviation the characteristics of the dextrocardiogram. Rotation of

FIG. 77. Abnormal axis deviation. *a*, left ventricular hypertrophy; *b*, right ventricular hypertrophy; vertical lines mark $\frac{1}{4}$ sec. (kindness of Dr. John Hepburn).

the heart may result from tumors, hypertrophy of the ventricle, etc. In the rare developmental anomaly—complete transposition of the heart (dextrocardia)—reversal of all the deflections of the electrocardiogram is seen. The heart lies with its apex pointing to the right. Displacement of the heart as a whole, as by a pleural effusion or pneumothorax, is less likely to produce changes in the electrocardiogram than when it undergoes rotation.

It has been mentioned above that division of one branch of the bundle disturbs the electrical balance of the heart; an abnormal deviation of the electrical axis to the right or left will be a result; interruption of a branch of the bundle by disease causes a similar distortion of the electrocardiogram

(see p. 192). In cardiac hypertrophy and ventricular extrasystoles abnormal deviation of the axis will also occur. Left bundle branch block, left ventricular hypertrophy and right ventricular extrasystoles (see fig. 77 and 82, p. 192) cause left axis deviation; right bundle branch block, right ventricular hypertrophy and left ventricular extrasystoles (see fig. 78) produce right axis deviation.

There has been a considerable amount of discussion concerning the mode of production of the electrocardiographic features of ventricular hypertrophy. The following explanations have been advanced.

(1) That it is due to the *greater mass of muscle*, the electrical changes occurring in the hypertrophied chamber overbalancing those of the normal

of these two factors is the most probable explanation of the characters of the electrocardiogram in ventricular hypertrophy.

THE T WAVE OR END DEFLECTION

There is not unanimity concerning the manner in which the T wave is produced. It is generally accepted, however, that while the QRS complex represents the invasion of the ventricle by the excitatory process, the T wave is produced by the latter's retreat, i.e., during the return of the muscle to the inactive state. Like the QRS complex the T wave is probably a composite effect of the two ventricles, but it is not due to the *arrival* of the excitation wave at the base (p. 183). It is to be remembered that when a muscle is either fully

FIG. 78. Diagram to illustrate right (beaded arrow) and left (interrupted arrow) axis deviation. Normal electrical axis shown by arrow with solid shaft. Electrocardiograms are for lead I.

side. This theory has been disproved by the discovery that the electrocardiographic features which were thought to be produced by one ventricle are actually produced by the other (p. 192). In other words, the electrical changes in the *sound* ventricle overbalance those of the hypertrophied side.

(2) *Altered position of the heart.* The greater mass of the hypertrophied ventricle causing rotation of the heart around its longitudinal axis; this probably plays only a minor rôle.

(3) *Slowed conduction over the bundle branch* supplying the hypertrophied ventricle as a result simply of the lengthening of the conduction pathway incident to the enlargement of the ventricular cavity, or to actual injury of the conducting tissue associated in some way with the cardiac disease. According to Barker and associates, one or other

active or completely at rest no potential difference exists between any of its parts and no current flows. The isoelectric interval from S to T represents the period during which the entire ventricular musculature is involved in the excitatory process and is spoken of by Lewis as the *stage of possession*, the Q, R, S and T complexes being referred to as the *stages of invasion* and *retreat* respectively. During the isoelectric period following the T wave (i.e., from T to P) the cardiac muscle is relaxed.

If the order of the retreat of the excitatory process were the same as the order of invasion, i.e., if those regions which were first excited were the first to recover and vice versa, one should expect that the deflection of the retreat, instead of being a single broad wave (T) would be simply a repetition of the QRS complex, but with the several waves reversed. An attempt to explain why the end effect is a single broad deflection is

based upon the belief that the period during which the heart returns to the completely inactive state is slower than the period of invasion of the muscle by the excitation wave. It is believed, moreover, that the excitation wave does not retreat from different parts of the musculature in the same order as it advanced. It does not necessarily disappear first from the region at which it first arrived. It is supposed, on the other hand, that the excitation wave recedes more rapidly from some regions than from others and, as a consequence, relatively large masses of the heart muscle become oppositely charged. It is this state of unbalanced electrical forces which is believed to be responsible for the T wave. In other words, the T wave is explained upon the basis of the theory of distributed potential differences which, as we have seen, is not acceptable as an explanation of the QRS deflections (p. 181). It has been suggested that the active state (negativity) lingers longer in the region of the base than at the apex. In support of the conception of a delay at the base the following observations may be cited.

In the frog, the end deflection is frequently inverted. If the process at the apex is hastened by the application of heat, or that at the base is slowed by cooling, an upright T wave is induced. Heat applied to the base or cold to the apex brings about the reverse effect—inversion of an upright wave. Wilson and Finch showed that the normal human subject gives an inverted T wave after swallowing iced water. The passage of the water along the esophagus cools the apex and delays the disappearance of the excitatory process. The possibility has been suggested that the upright T in the normal electrocardiogram is due to a difference in temperature of the basal and apical regions (the former being in closer proximity to pulmonary tissue, the latter to the liver). It is not known, however, whether or not such a temperature difference actually exists.

A different explanation of the origin of the T wave has been advanced by Hoff and Nahun. They discard the "base-apex" theory, believing that the T wave is caused by interference between the terminal deflections of the dextrocardiogram and the levocardiogram. Normally the terminal deflections of the dextrocardiogram predominate and the T wave is upward in direction, but any condition which tends to prolong the electrical changes of the left ventricle or shorten those of the right was found to cause inversion of the T wave. Thus heating the right ventricle of the dog's heart or cooling the left was found to convert an upright T wave to an inverted one.

Conditions associated with flattening or inversion of the T wave. Vagal and sympathetic stimulation may be followed by inversion of the T wave. Inversion also appears in the early stages of digitalis poisoning; after the administration of adrenaline, quinidine and other drugs; and in acute infections. In these instances there may be little or no alteration in the QRS complex. Inversion of the T wave in leads I and II is taken in general as a very unfavorable sign and frequently accompanies grave cardiac disease. But though it is true that in a series of cases showing persistently an inverted T the duration of life is shorter than in those in which it is upright, the direction of the wave nevertheless cannot be relied upon alone in arriving at the prognosis of an individual case. The deflection may be inverted in temporary and comparatively unimportant conditions, or it may be upright though a fatal termination from cardiac failure is imminent. Flattening or slight inversion of T in lead III is of no significance; it may occur in perfectly normal persons.

FIG. 79. Upper tracing from jugular vein, lower from carotid artery. AL, alignment marks (after Price).

THE VENOUS PULSE

Pulsation in the large veins at the root of the neck is a normal phenomenon which can be demonstrated by means of special apparatus. It is only under abnormal conditions, however, and then only occasionally that the pulsations are visible to the eye. Valuable information concerning the events of the cardiac cycle from an experimental as well as from a clinical point of view can be gained by a study of jugular pulse records.

The pulsations occurring in the jugular bulb are the result of pressure changes occurring within the right auricle. Since the vein is in direct communication with the interior of the auricle, changes in volume and pressure, which correspond closely to the pressure fluctuations of the intra-auricular pressure curve, are transmitted to the column of venous blood. The intra-auricular pressure is influenced by events occurring not only in the auricle itself but by pressure changes transmitted from the ventricle. For this reason a study of the

waves of a jugular tracing enables the true relations of the different events of the cardiac cycle (auricular and ventricular) to be determined. The jugular tracing though the counterpart in a qualitative sense of the intra-auricular pressure curve, gives no quantitative information, being a record of volume and relative pressure changes only, and no criterion of the absolute pressure values developed in the auricle. The waves *c* and *v* represent ventricular events and are in consequence spoken of as the ventricular complex. The interval between the commencements of the *a* and *c* waves (*a-c* interval) indicates the time elapsing between auricular and ventricular systoles and its duration is an index of the conduction rate between the two chambers.

The waves of the venous pulse are given the same lettering as those of the auricular pressure curve (p. 170). Their main features are

Positive wave *a* due to auricular systole.

Negative wave *x* due to commencement of auricular relaxation.

Positive wave *c* due to ventricular contraction and bulging of A-V valves into the auricle.

Negative wave *x*¹ due to drawing down of A-V septum and the discharge of blood from the thoracic cavity.

Positive wave *v* due to filling of auricle which is closed below by A-V valves.

Negative wave *y* due to opening of A-V valves and emptying of auricle into the ventricle.

In figure 79 is shown a typical venous pulse. The waves show their distinctive characters which may be recognized almost at a glance. Venous tracings from a clinical case, however, are frequently atypical and present a confused series of irregular waves which are impossible to identify by mere inspection. Sometimes successive waves, for instance, *a* and *c*, or *v* and *a*, are merged together. At other times certain waves are absent. We must then have recourse to some method

of distinguishing the various fluctuations in order to interpret the tracing. An arterial tracing serves as a key. In figure 64 (p. 171) the intracardiac, venous, and arterial curves are accurately superimposed; that is, they all commence at the same instant. Consequently synchronous events lie along vertical lines intersecting the several tracings. In the case of the jugular tracing the commencement of the upstroke of the carotid is synchronous with the commencement of the *c* wave. The upstroke of the carotid or of the radial artery is practically always a landmark which is clearly discernible. Therefore, if one could take a venous tracing accurately superimposed with a carotid tracing, a vertical line drawn through the commencement of the upstroke of the latter would when extended through the venous curve indicate the commencement of the *c* wave. It is not feasible, however, to do this, but the time relations of the two writing levers can be correlated by means of what are known as *alignment marks*. That is, while the writing surface is at rest the two levers are given a light tap so that each makes an upright mark. The marks are used as points from which measurements may be made and the two tracings synchronized in an indirect way. Thus (cf. fig. 79) the distance from the alignment mark AL to the carotid upstroke is measured. This distance is then laid off upon the venous tracing commencing from the alignment mark AL. It will indicate a point on the jugular tracing corresponding to the commencement of the *c* wave. When the arterial tracing is taken from the radial, as is most commonly done, the procedure is the same, except that a distance representing $\frac{1}{10}$ second, obtained from the time tracing, must be deducted from the measurement. This is the difference in the times of arrival of the pulse at the carotid and the radial. The instrument employed for the clinical registration of jugular and arterial pulses, and originally devised by Mackenzie, is known as the *polygraph*.

In determining the length of the arterial pulse wave (p. 150) a procedure similar to that just described is followed in timing the successive arrival of the wave at two points in the arterial tree.

CHAPTER XXIV

DISORDERS OF THE HEART BEAT AND THEIR INVESTIGATION BY GRAPHIC METHODS

The following is a convenient classification of cardiac irregularities:

A. Affections of rhythm due to impaired conduction through the A-V bundle and its ramifications

I. Stem of bundle

- (1) Delayed conduction
- (2) Missed beats, partial heart block
- (3) Complete heart block

II. Bundle branch defects

B. Affections due to abnormal impulse formation

I. Extrasystoles

- (1) Ventricular
- (2) Nodal
- (3) Auricular

II. Paroxysmal tachycardia

Auricular, nodal and ventricular

III. Auricular flutter

IV. Auricular fibrillation

V. Ventricular fibrillation

C. Alternation of the heart

D. Affections due to vagal influences

- I. Sinus arrhythmia
- II. Phasic irregularity
- III. Sinus bradycardia
- IV. Sino-auricular block

A. AFFECTIONS OF RHYTHM RESULTING FROM IMPAIRED CONDUCTION

I. IN THE A-V NODE OR STEM OF THE BUNDLE—AURICULO-VENTRICULAR BLOCK

In animals, conduction from auricle to ventricle can be depressed or blocked by crushing, cutting, or the application of cold to the A-V bundle. This strategic point in the pathway of the excitation wave is also attacked by disease, and conduction through it may be depressed or completely abolished. Depression of conduction through the node or bundle varies in degree. Three stages are recognized.

(1) Delayed conduction

In this stage conduction is merely slowed; every impulse reaches the ventricle. The intervals between the auricular and ventricular systoles (A-V_s intervals) are lengthened and may have a

duration of 0.5 second, though, as a rule, they are considerably shorter than this. The condition can be recognized only by means of the electrocardiograph or a venous pulse tracing. Lengthening of the P-R interval in the former tracing, or of the *a-c* interval in the latter, beyond the normal maximum of 0.2 second is taken to indicate delayed conduction (fig. 80).

(2) Missed beats—partial heart block

When impaired conduction reaches a certain degree, impulses from time to time fail to reach the ventricle, and a beat is missed. The auricular beats are perfectly regular, and in this way the condition differs from sino-auricular block (p. 204). A ventricular beat may be missed only occasionally and at irregular intervals. The P-R or the *a-c* intervals may generally, though not invariably, be seen to lengthen progressively for several heart cycles preceding the dropped beat. The interval of the cycle succeeding the missed beat is shortened again to near the normal length. In a further stage of the condition the beats are dropped more frequently and may be spaced either at regular or irregular intervals in the tracing. When the grade of block is still more advanced, impulses fail to penetrate the bundle after every second auricular beat; or three, or even four auricular contractions may occur before an impulse reaches the ventricle, i.e., the ventricle responds only to every third or fourth auricular beat. So, an auriculo-ventricular rhythm becomes established in which the two chambers beat in the ratio of 2:1, 3:1, or 4:1. The first of these is seen most frequently, the second is the least common (fig. 80).

(3) Complete heart block

When the A-V node or bundle offers an absolute barrier to the passage of the impulse, the dissociation of the rhythms of the two ventricles is complete (fig. 81). The auricle beats at its own rate of about 70 per minute and the ventricle at its inherent rate of about 35. The latter is then spoken of as the idio-ventricular rhythm. Both ventricles beat simultaneously. This fact suggests that when the ventricle assumes this rate it is

under the control of some single region possessing the power of rhythmical activity. From experimental investigation it appears that the controlling center is the A-V bundle below the site of the lesion. The speed with which a particular region of the heart can develop and discharge impulses apparently determines its ability to dominate

Partial and complete heart block are accompanied by changes in the rhythm of the arterial pulse. When beats are missed occasionally the pulse intermits either at regular or irregular intervals. In the more fully developed conditions marked slowing (bradycardia) of the pulse occurs. Visible pulsations in the veins at the root of the neck may occur, for the auricle, in con-

FIG. 80. Upper tracing, delayed conduction, lead I. Lower tracing, incomplete heart block, lead I (missed beats). (Kindness of Dr. John Hepburn.) The diagram below (after Lewis) represents incomplete heartblock. The thin rectangles, A, represent contractions of the auricle, the thicker ones, V, contractions of the ventricle. The obliquely directed lines represent conduction over the A.V. bundle; the slower the conduction rate the more oblique the line. The gaps in the lower rectangles indicates missed beats of the ventricle. It will be noted that delay in conduction increases progressively in successive cycles until a beat is missed. Heavy vertical lines = $\frac{1}{2}$ sec.

FIG. 81. Complete heart block, lead I (kindness of Dr. John Hepburn).

other regions. It has been mentioned that when a region of higher rhythmicity is destroyed or isolated the region next in order of rhythmical power assumes the rôle of pacemaker (p. 163, 206). When, for instance, the S-A node is destroyed or isolated the A-V node assumes control, and when this or the upper part of the bundle is separated from the tract of tissue below, the lower lying portion takes over the government of the ventricular rate.

tracting upon a larger volume of blood accumulated as a result of the infrequency of the ventricular contractions, causes a pronounced wave to be transmitted along the jugular. A certain proportion of the venous pulsations may be seen to be unassociated with an arterial pulse. Sometimes a sound may be heard over the heart at the time of the isolated venous pulsation since the auricular contraction is unusually forceful and the sound vibrations thus set up are not smothered by the first heart sound which, in the normally beating heart, follows so closely upon auricular systole.

The venous pulse tracing and electrocardiogram show characteristic features. The *a* and P waves of the respective records occur at the usual times, but the ventricular complex (*c* and *v* in the venous curve and QRS and T in the electrocardiogram) is absent, a gap appearing in the tracing each time a beat of the ventricle is missed. In incomplete heart block, as one would expect, a relationship between a ventricular complex and a preceding auricular wave can always be made out, whereas in complete block there is no relationship. In the venous pulse, for example, the *a* and *c* waves may occur simultaneously, and produce a large *a + c* wave. Or the *a* and *v* waves may coincide. Corresponding effects are produced upon the electrocardiogram.

Temporary heart block may result from various toxic agents, e.g., digitalis, strophanthus, quinidine, etc., which exert a specific effect in depressing auriculo-ventricular conduction. Heart block may be a sequel or an accompaniment of several acute infectious maladies, e.g., diphtheria, rheumatic fever, etc. It is produced in animals by asphyxia (p. 214). Increased vagal tone is sometimes responsible for delayed conduction over the A-V bundle. Partial heart block is not uncommonly seen in the course of rheumatic fever and is then, in many instances, of vagal origin, being temporarily abolished by atropine.

Stokes-Adams syndrome. This condition was first described by Adams (1827) and later by Stokes (1842). Its features are a slow pulse and syncopal attacks or convulsive seizures, usually epileptiform in character. The term includes any condition of vascular origin in which these features are associated, and it is probable that the underlying morbid state upon which the syndrome depends is not identical in all instances (see also carotic sinus, p. 241). In the majority, however, the slowed cardiac action is the result of heart block, and the cerebral symptoms are the direct result of the bradycardia. The prolonged pause between beats permits the diastolic pressure to fall to a low level; the blood supply to the cerebral centers suffers in consequence. Hardening of the larger arteries or aortic regurgitation, etc. when present in association with heart block, must enhance the effect of the bradycardia upon the diastolic pressure. That heart block alone is capable, however, of causing the syndrome was shown by Erlanger and Blackman (p. 166) who reported similar syncopal and convulsive seizures in dogs after division of the bundle. Adrenaline or ephedrin has been employed with some success.

II. BUNDLE BRANCH DEFECTS—INTRA-VENTRICULAR BLOCK

When one or other of the primary divisions of the bundle is blocked by disease the impulses reach the muscle of the two ventricles asynchronously. The ventricle of the sound side is activated a fraction of a second before the other. The affected

ventricle is excited later by the escape of the impulse from the healthy side through the septum (p. 185). The imbalance between the electrical effects in the two ventricles produces characteristic electrocardiographic features. Bundle branch block is most commonly associated with coronary disease. The left branch of the bundle is involved five times more frequently than the right (see also p. 186).

From his experiments upon animals (p. 185) Lewis concluded that a clinical record having the characters of a levocardiogram (main deflection of the QRS group *upward* in lead I and *downward* in lead III) or of a dextrocardiogram (main deflection of the QRS group *downward* in lead I and

FIG. 82. *a*, left bundle branch block; *b*, right bundle branch block. Note lengthening of QRS. Compare with fig. 79 (kindness of Dr. John Hepburn).

upward in lead III) was due to disease of the *right* or *left* bundle branch respectively. Reports of post-mortem examinations of the conducting system of subjects which had shown the characteristics of a levocardiogram during life also supported this conclusion since the *right* branch was said to be diseased. Barker, MacLeod and Alexander, however, stimulated the surface of the exposed human heart and obtained extrasystoles (p. 193) whose characters indicated that the so-called levocardiogram is produced by the right ventricle and the dextrocardiogram by the left. They conclude therefore that a record in which the main initial deflection is upward in lead I and downward in lead III—the so-called levocardiogram—is due to disease of the *left* bundle branch and that an

electrocardiogram in which the main initial deflection is downward in lead I and upward in lead III—the so-called dextrocardiogram—is due to disease of the *right* branch. In other words, the electrocardiogram which has hitherto been ascribed to a lesion of the right branch is actually due to disease of the left branch and vice versa (see fig. 82). The difference between the results

FIG. 83. (After Lewis). I. A diagram illustrating disturbance of the heart's mechanism when a systole is caused by exciting the ventricle during diastole. Ic, initial cycle; Fc, forced or extrasystolic cycle; Rc, returning cycle; and Rsc, restored cycles. p is the premature or forced beat. Note that the auricular rhythm remains undisturbed. The forced and returning cycles are together equal in length to two initial cycles. II. A diagram illustrating the events when a premature contraction is excited from the pacemaker. Stimulus production in the tissue which originates the heart rhythm is indicated by the line S.P.; the impulse is supposed to discharge when it reaches the line xx' and to fall at each contraction of the heart to the level yy' . c and d are equal in length. III. A diagram illustrating a premature beat arising in the A-V node.

of experiments upon the dog and clinical cases is ascribed by Wilson and his associates to the fact that the direction of the anatomical axis of the heart and the inclinations of the intraventricular septum in this animal are not the same as they are in the human subject. Strands of conducting tissue also cross the right cavity of the canine heart which are absent in the human heart. Roberts and associates in experiments upon the cat and the monkey, also found that division of the right branch produced a record in which the main

initial deflection was downward in lead I and upward in lead III. Opposite effects resulted from division of the left branch.

The direction of the T wave (upward or downward) is usually opposite to that of the main deflection of the QRS group. Thus in disease of the right branch the T wave has the normal direction in lead I but is inverted in lead III. Bundle branch disease is of the gravest significance, the subject rarely surviving many months after it has been discovered. The electrocardiograph is the only means by which it can be recognized. Distortion of the electrocardiogram similar in type to that seen in bundle branch block occurs in other conditions (p. 185) but a distinguishing feature of the former is lengthening of the QRS complex beyond the normal maximum of $\frac{1}{10}$ second. In disease of the left branch of the bundle the Q-E interval is prolonged owing to the lag in ventricular ejection.

B. DISTURBANCES OF RHYTHM DUE TO ABNORMAL IMPULSE FORMATION

I. EXTRASYSTOLES OR PREMATURE CONTRACTIONS

An extrasystole can be induced experimentally by stimulating the cardiac muscle at any time except during its phase of absolute refractoriness (p. 155). Extrasystoles occur in the human heart as a result of some abnormal process of impulse formation. Though extrasystoles may be associated with organic heart disease they more frequently occur in its absence; they may then be of reflex origin initiated from the abdominal viscera or be due to some form of intoxication, e.g., digitalis, chloroform anesthesia, hyperthyroidism, excessive smoking, etc. Beattie, Brow and Long produced extrasystoles in cats by stimulation of the hypothalamus (p. 883), and their occurrence in man following brain lesions has been reported by Lucke and by Korth, which indicates that in some instances they are of central origin. The auricle or the ventricle may be the site of origin of the premature contraction, or the extra impulse may arise in the A-V node (see diagrams, fig. 83).

(1) Ventricular extrasystoles

The premature contraction occurs after the normal ventricular beat has ceased and the muscle has recovered from its absolute refractory state. It is not preceded by an auricular contraction, and is not dependent upon an impulse received from the upper chamber (fig. 84). The premature contraction is followed by a long pause. This is

usually of just sufficient duration to cause the succeeding normal ventricular beat to occur at the instant that it would have occurred had there been no premature contraction. The cause of this *compensatory pause* has been explained elsewhere (p. 155). Briefly, it is due to the normal impulse reaching the ventricle when the muscle is still refractory as a result of the premature beat. The interval between the normal beat and the one following the premature contraction is therefore equal in length to two normal cardiac cycles (fig. 83, I). Sometimes, however, when the extrasystole occurs early in diastole and the heart rate is slow there may be no compensatory pause. The auricular impulse then reaches the ventricular muscle after it has recovered from the refractory state resulting from the premature beat; the auricular impulse therefore brings about a response at, or (as a result of some lengthening of the A-V₁ interval following the premature beat) slightly

FIG. 84. Ventricular extrasystoles (bigeminal pulse, p. 196) arising in right ventricle—left axis deviation (p. 186). (Kindness of Dr. John Hepburn.)

after the usual time. The normal ventricular systoles are then all equally or nearly equally spaced and the extra contractions are interposed here and there between them. That is, the time interval from the normal beat preceding the extra contraction to that following it is of normal length or but slightly lengthened. Premature beats of this nature are called *interpolated extrasystoles*.¹

(2) Auricular extrasystoles

The premature contraction arises in the auricle at some point outside the S-A node. The abnormal impulse reaches the ventricle along the usual paths and evokes a ventricular contraction, unless the auricular beat is so premature that sufficient time has not elapsed to permit the recovery of the ventricular muscle from its refractory state. The latter, except for its time relations, is approxi-

¹It should be noted that except in the case of interpolated beats there is not an extra or additional beat, as the term extrasystole seems to imply. The premature beat, in effect, displaces the normal beat.

mately normal. An auricular extrasystole, therefore, causes a premature contraction of the whole heart. The premature auricular beat prevents the occurrence of the next normal auricular impulse and the pause of the auricle which follows the abnormal auricular contraction is usually precisely equal to a normal interval. This fact has been explained upon the assumption that, normally, impulse formation in the S-A node is the result of the liberation of energy which has been built up during the previous quiescent period. Upon the occurrence of the abnormal impulse this store of energy, accumulated for the normal impulse, is discharged and a definite time interval must elapse before it is again built up to the required level. (See fig. 83, II.) Sometimes, however, the interval following the premature contraction is slightly lengthened, suggesting that the rate at which the S-A node builds up its store of energy is lowered. In any event, there is rarely a long (compensatory) pause following the beat of the *ventricle*, the interval between the two normal beats, i.e., from the beat preceding to the one succeeding the premature contraction, being nearly always shorter than two normal cycles. In other words, the normal auricular impulse following the premature auricular contraction upon reaching the ventricle does not "miss-fire," as in the case of ventricular extrasystole, but calls forth a response from the ventricle.

(3) Nodal extrasystoles

Extrasystoles occur sometimes as a result of impulse formation in the A-V node or supraventricular part (stem) of the bundle. On account of its central position between the two chambers, impulses arising in the A-V node pass upward and downward to cause simultaneous or nearly simultaneous responses from auricle and ventricle. Sometimes the ventricular contraction may actually occur first, in which case it is suggested that the impulse has arisen in the stem of the bundle and so has its course to the ventricular muscle considerably shortened. The extra cycle is usually, though not invariably, followed by a compensatory pause (fig. 83, III).

In rare instances extrasystoles arise as a result of abnormal impulses initiated in the sino-auricular node—*sinus extrasystoles*. Except for the interposition of the extra beat the rhythm of auricles and ventricles is but little disturbed. The interval following the extra beat is normal in length or slightly shortened.

The effects of extrasystoles upon the characters of the electrocardiogram and of the arterial pulse

THE ELECTROCARDIOGRAM. In *ventricular extrasystoles* the electrocardiogram shows irregularity in the spacing of the ventricular complexes. The following characteristics are found:

(1) The intervals between the R wave caused by the premature beat and the corresponding waves of the normal beats preceding and following it, respectively, are altered in length. The interval between the last normal R wave and the premature R wave is short, while the interval following this to the next normal R wave is prolonged—compensatory pause. The time elapsing between the two normal R waves is usually equal to the length of two normal cycles.

(2) The premature R wave is not preceded by a P wave. Since the premature ventricular contraction occurs unrelated to auricular systole it frequently happens that a normal contraction of the auricle occurs about the same time as the ventricular extrasystole. P and R waves then become fused. At other times the P wave follows closely upon the premature R wave.

(3) The P waves are equally spaced and some appear which are not succeeded by a ventricular complex (refractory period of the ventricular muscle). In the case of the *interpolated* type of extrasystole, however, each P wave is followed by an R wave, and no long pause is seen.

(4) Ventricular extrasystoles also show abnormalities of the QRS complex which distinguish them from premature contractions of auricular or nodal origin. An impulse arising in the heart below the point where the bundle forks will activate one ventricle slightly in advance of the other. It is to be expected then that the QRS deflections of the electrocardiogram will be a record of unbalanced electrical effects. This is actually the case (fig. 84). In other words, if the extrasystole arises in the left ventricle its record will be deformed much in the same manner as that already described (p. 192) for right bundle branch block (right axis deviation—main initial deflection downward in lead I and upward in lead III). If the premature beat arises in the right ventricle the electrocardiogram will show the features of a left branch defect (left axis deviation—main initial deflection upward in lead I and downward lead III).

In *auricular extrasystoles* the electrocardiogram shows disturbances in the timing of both the auricular and the ventricular complexes, but, as

already mentioned (p. 194), a normal or only a slightly lengthened pause follows the extra beat. The P waves are unequally spaced but each is followed by a ventricular complex. The abnormal auricular wave may coincide with and be buried in the QRS complex of the preceding normal cycle.

The records of *extrasystoles arising in the A-V node* or supraventricular part of the bundle are variable according to the timing of the auricular and ventricular contractions. When the auricles and ventricles are excited simultaneously the P and R waves become fused. When the two chambers are not activated simultaneously, the P precedes the R wave by a short interval, or the order of the waves may be reversed (R-P interval).

THE ARTERIAL PULSE. It has been demonstrated that several long-recognized irregularities of the pulse are the result of extrasystoles. For example, in the irregularity known as *intermittent*

FIG. 85. (After Price.) a, intermission of the pulse; b, pulsus bigeminus, due to a single extrasystole with its succeeding compensatory pause occurring regularly after each normal beat. *Ex.S.*, extrasystole.

pulse there appear from time to time relatively long intervals during which no beat is felt in the radial (fig. 85, a). The intervals are most pronounced when a premature contraction of the ventricle which is too weak to open the semilunar valves occurs. This most commonly happens when the heart muscle receives the abnormal impulse during the earlier part of its relative refractory phase. The premature beat may be detected by hearing a faint first heart sound which is not succeeded by a second sound (p. 175). No pulse is produced in the radial at the time, nevertheless the extrasystole may be followed by a compensatory pause, and graphic records show as a rule that the gap in the radial tracing is just equal to two normal cycles. That is, a beat is dropped completely from the arterial record. The detection of an extra contraction of the ventricle, however, enables the irregularity to be distinguished from the missed beats of partial heart block (p. 190) which may give an arterial tracing with similar characters.

If ventricular extrasystoles which fail to open the semilunar valves are repeated after each normal beat, the long intervals separating the latter will cause pronounced slowing of the pulse rate. The pauses between the arterial pulses are doubled in length and the pulse frequency as a consequence is reduced to half the normal. Bradycardia produced in this way and sometimes termed *false heart block* is distinguished from true heart block by a study of the venous pulse or the electrocardiogram which reveals the extra ventricular complexes; or the faint sounds of the extra contractions may be heard upon auscultation.

FIG. 86. Top tracing, auricular tachycardia; middle tracing, nodal tachycardia; bottom tracing, ventricular tachycardia. (Kindness of Dr. John Hepburn.)

When the extrasystoles are forceful enough to open the semilunar valves, and occur regularly one after each normal systole, paired pulse beats, each couple being followed by a long pause, are felt in the radial (fig. 85, b). This type of pulse irregularity, which is sometimes seen following overdosage with digitalis, is called the *bigeminal pulse* (*pulsus bigeminus*).

II. PAROXYSMAL TACHYCARDIA

This may be defined as a condition in which the rate of the heart is greatly accelerated for a longer or shorter period without obvious cause. The rate varies in different cases from 120 to 250 per minute. The onset of the paroxysm is sudden and the increased rate is maintained for a variable length of time with perfect regularity, successive

cycles usually not varying in length by more than a hundredth of a second. The paroxysm lasts for only a few beats in some instances, in others it persists for a few minutes, hours or even days, though attacks of more than ten days duration are very rare (Lewis). The attack ceases as abruptly as it commenced, the heart resuming its normal rate almost instantly.

The paroxysm, it is believed, consists of a series of rapidly recurring extrasystoles which completely submerge the physiological rhythm. The site of origin of the extrasystoles, as in the case of single premature beats, may be in the *auricle*, the *A-V node or stem of the bundle*, or in the *ventricle* (fig. 86). The auricular type is the most common; each auricular impulse spreads to the ventricle and causes a contraction whose features as indicated by the electrocardiogram are normal. The P wave is frequently inverted.

When the impulses arise in the A-V node or supra-ventricular part of the bundle, the P-R intervals of the electrocardiogram are shortened. Inversion of the P waves is common. Or, the contractions of the two chambers may be simultaneous, the P waves being then buried in the ventricular (QRS) complexes. Again, the contraction of the ventricle may occur before that of the auricle; it then sometimes happens that a progressive lengthening of the intervals between the R and P waves (R-P interval) of the electrocardiogram is seen; ultimately an auricular beat is missed. This is termed *reversed heart block*. In other instances, as the R-P intervals reach a certain length, a contraction of the ventricle occurs prematurely, and is not followed by a contraction of the auricle. It is thought that the ventricular contraction is caused by the same impulse that caused the preceding auricular beat. That is, the impulse arising in the node first excites the auricle, then re-enters the junctional tissue, which has now recovered from its refractory phase, and passes downwards to the ventricle. This is spoken of as *reciprocal rhythm*.

When the impulses arise in the ventricle the QRS complexes have the characteristics of those caused by ventricular extrasystoles (p. 193). The auricular rhythm is usually undisturbed but occasionally it is abnormal, for, when a series of rapidly recurring contractions arises in the ventricle the impulses may pass along the bundle in a retrograde fashion and activate the auricle to the exclusion of the normal impulse. In other words, the ventricle then sets the pace and the auricle follows. In such instances the P waves are inverted and succeed the QRS deflections, or are buried in the ventricular complexes as in the nodal type mentioned above.

III. AURICULAR FLUTTER

There are two forms of this disorder, *pure* and *impure flutter*. In both types the auricle beats

at the phenomenally rapid rate of from 200 to 400 beats per minute, but in pure flutter the rhythm is regular, in impure flutter it is irregular. Flutter differs from paroxysmal tachycardia in the following particulars.

(a) The auricular rate of beating is usually much greater than that seen in paroxysmal tachycardia.

(b) The disorder is of much longer duration, persisting unchanged for months or years, though it is sometimes transient.

(c) The ventricle fails as a rule to follow the rate of the auricle; a state of relative heart block becomes established as a result of the comparatively long refractory phase of the junctional tissue.

(d) It is produced (p. 199) by the passage of the impulse over one or more circular pathways—*circus movement*.

Auricular flutter may become converted to paroxysmal tachycardia.

In pure flutter the rhythm is remarkably regular (fig. 87). The lengths of the auricular cycles vary

FIG. 87. Pure flutter with a ventricular extrasystole (kindness of Dr. John Hepburn).

no more than a few thousandths of a second over comparatively long periods. In impure flutter this constancy of cycle length is not seen and varying degrees of irregularity occur. In flutter the auricular walls do not completely relax. That is, though the proportion of active to inactive fibers varies during the rapid beating, at no one time are all the fibers in the relaxed state (p. 170). In the electrocardiogram, therefore, the level of the tracing between the P waves lies for the most part above the isopotential line, only touching the latter for an instant. The level of the tracing is continually changing and the electrical changes of the auricle are carried over to alter the form of the ventricular complex. On the other hand, the fibers are never all contracted at the same time, so that auricular systole as well as diastole is incomplete.

The ventricle rarely keeps pace with the racing auricle, the refractory phase of the conducting tissue being longer as compared with that of the auricular muscle. As a consequence, a state of

relative heart blocks develops and an auriculo-ventricular rhythm of 2 to 1, or less frequently, of 3 to 1 or 4 to 1, becomes established. Should the ventricle respond to each beat of the auricle, as occasionally happens, serious circulatory disturbances follow; ventricular diastole is so shortened that the ventricle receives a greatly reduced load of blood. The output of the heart may be so reduced as a result that loss of consciousness resulting in death may follow.

IV. AURICULAR FIBRILLATION

This condition so far as fundamental causes are concerned may be looked upon as an advanced stage of flutter. The auricular muscle is the seat of incomplete contractions which recur at a frequency of from 400 to 600 per minute. So incomplete are the contractions and so rapidly are they produced that the individual beats are scarcely distinguishable from one another. The auricular cavity is never emptied of blood and its wall is a quivering sheet of muscle. Auricular fibrillation is the most common of all the serious cardiac irregularities, being associated, according to Lewis, in 60 to 70 per cent of all cases of cardiac failure in hospital practice. It is most frequently seen in mitral stenosis and in thyrotoxicosis (p. 675). It rarely occurs in the absence of myocardial disease.

Only a proportion of the auricular impulses pass through the A-V bundle and activate the ventricle. The relatively long refractory period of the conducting tissue shields the ventricle from the high rate of the auricular beating. The arterial pulse, nevertheless, is usually considerably faster than the normal (100 to 150) though it may be normal or even slowed. Those impulses which reach the ventricle do so in a somewhat haphazard manner, and indeed one of the most characteristic features of fibrillation of the auricles is absolute irregularity in the rate and force of the ventricular beats. These features are expressed in the terms "*delirium cordis*," "*complete irregularity of the pulse*" or "*perpetual arrhythmia*," which were applied to the condition before its true nature was recognized. A proportion of the heart beats are frequently so weak that they fail to cause a pulse in the radial. The apex beat is therefore much more rapid than the pulse. The former, for example, may be 150 and the latter only 60 or 70. The difference is called the *pulse deficit*. With treatment and improvement in the condition of the cardiac muscle the pulse rate therefore may increase.

The venous pulse in auricular fibrillation is of the ventricular form, a waves are absent, being represented by a series of rapid vibratory waves (f waves). Similarly in the electrocardiogram, small rapid undulations replace the P waves (fig. 88).

V. VENTRICULAR FIBRILLATION

The ventricular muscle may pass into a state of rapid, tremulous and ineffectual contractions closely similar in nature to the condition just described as occurring in the auricle. In animals, ventricular fibrillation may be initiated by direct electrical stimulation of the ventricular muscle, as was first shown by Ludwig in 1850. Mechanical stimulation of the ventricle, especially by pricking the tissue in the A-V groove, ligation of a coronary artery (Porter) or certain chemicals and drugs in excess, e.g., digitalis or calcium chloride, may induce fibrillation. Levy found that chloroform anesthesia renders the hearts of experimental animals (cats) highly susceptible to fibrillation.

FIG. 88. Auricular fibrillation, lead 2 (after Lewis).

A mere touch of a finger or instrument, the stimulation of a sensory nerve, section of the vagi or their paralysis by atropine, may set the ventricle fibrillating. The heart behaves as though sensitized by the anesthetic and ready at the least provocation to fibrillate. Adrenaline was found to greatly enhance the effect of chloroform—a fact which indicates the danger of adrenaline administration while a subject is under the effect of this anesthetic. Fibrillation may also ensue spontaneously under chloroform and Levy found that the condition is more likely to supervene when the animal is passing from deep to light anesthesia. Cyclopropane, like chloroform, has the effect of sensitizing the heart to the action of adrenaline in inducing ventricular tachycardia and fibrillation, but these cardiac irregularities are rarely seen under ether anesthesia. Quinidine reduces the susceptibility to fibrillation during cyclopropane anesthesia.

The effects of ventricular fibrillation upon the circulation are incomparably more serious than those of the corresponding auricular condition. This is evident when the importance of the two musculatures in the dynamics of the circulation are compared (p. 170). In fibrillation of the

lower chamber the propulsive force of its contraction is practically abolished and the circulation comes to an end; death follows within a few minutes.

From experiments upon animals it is believed that many instances of cardiac failure in patients under chloroform are due to fibrillation of the ventricles. This is generally considered to be of sudden onset, but it has been shown that when the condition is induced in animals by chloroform it is frequently ushered in gradually. A solitary extrasystole first occurs, which is followed after a time by coupling, tripling, and later by short runs of extrasystoles. Longer paroxysms of rapid beating follow. Finally as the tachycardia becomes more rapid it merges into fibrillation.

When fibrillation is induced suddenly as by electric shock its development may be somewhat different. According to Wiggers and his associates, only the first contraction is a true premature beat; those which follow are caused by re-entry of the excitation wave. These investigators, who induced ventricular fibrillation in dogs by the application of a single strong induction shock to the ventricle late in systole, recognize four stages in the development of fibrillation. In the *first* or *undulatory stage*, which lasts for only a second or two, the contractions are rapidly repeated but do not follow the same course over the surface of the ventricle; the electrocardiographic deflections show considerable variability in form. In the *second* stage of *convulsive inco-ordination*, which lasts for from 15 to 40 seconds, the contractions are more frequent and involve smaller areas of the ventricular muscle. The contractions of different areas of the muscle are out of phase so that the ventricle appears to be pulled about convulsively. The *third* stage of *tremulous inco-ordination* lasts for 2 or 3 minutes, the surface of the muscle is broken up into independently contracting areas of ever-decreasing size which are out of phase with one another. Thus, a tremulous appearance is given to the ventricles. The *final* stage of *atonic fibrillation* develops when the developing anoxia of the cardiac muscle causes weakening of its contractile force. This stage appears usually within from 2 to 5 minutes following the first stage and is marked by weak contractions or wavelets which travel only a short distance over the ventricular surface. It ends in complete cessation of all activity.

Ventricular fibrillation in man may result from:—

- a) Electric Shocks—electrocution, lightning stroke.
- b) Chloroform or cyclopropane anesthesia.
- c) Coronary occlusion and other causes of severe anoxia.
- d) Trauma to heart or chest wall.
- e) Ventricular paroxysmal tachycardia, in which fibrillation may be a terminal event.
- f) Toxic doses of digitalis or quinidine.
- g) Various diseases during the death agony.

Ventricular fibrillation, though usually fatal is not

invariably so, for rare instances have been reported in which the ventricles after fibrillating for a brief period resumed their normal rate and recovery occurred. Two methods, chemical and electrical, have been used in attempts to restore the normal rhythm to the fibrillating ventricles. Hooker has shown the efficacy of an excess of potassium in stopping fibrillation and of calcium in restoring the normal beat in the hearts of dogs subjected to electric shock. A 0.5 per cent solution of KCl is injected under pressure into the carotid toward the heart, so that it reaches the coronary system. This stops the heart. When a 0.023 solution of CaCl_2 is then introduced by the same route, the normal cardiac rhythm, in a successful experiment, is restored. Hooker and his associates showed that defibrillation of the dog's heart can be accomplished and the normal beat restored if a countershock, consisting of an alternating current of about one ampere is passed through the heart. In fibrillation due to anoxia (e.g. caused by coronary occlusion) the heart may be defibrillated by either of these two means but the heart muscle is usually unable to develop a forceful contraction owing to the oxygen lack. Wiggers has modified Hooker's procedure by sending into the heart a series of shocks (3-7) of about one second duration and one or two seconds apart. He recommends that when fibrillation follows coronary occlusion cardiac massage should be practiced while the countershocks are being given, in order to increase the blood flow to the ventricular muscle. In fibrillation due to electrocution or other cause, the countershocks may be applied through the chest wall although much stronger currents (20-30 amperes) will be required. It is obvious, however, that any method devised for the resuscitation of the fibrillating human heart has little practical application on account of the short time which the heart survives, even though the necessary equipment were on the spot.

THE UNDERLYING PROCESSES CONCERNED IN THE PRODUCTION OF FLUTTER AND FIBRILLATION. CIRCUS MOVEMENT. The observation that flutter and fibrillation could be induced in animals by electrical stimulation of the auricle has led to a much clearer understanding of the nature of these disorders in the human subject.

The three conditions, namely, pure and impure flutter and auricular fibrillation, are believed to be due to a disturbance of impulse initiation and transmission which is of fundamentally the same nature in all three, but varies in degree in each. Pure flutter represents a less advanced stage of the disturbance which in its highest degree leads to fibrillation. Impure flutter is a connecting link between the two. Evidence has been obtained by Mines, by Garrey and by Lewis and his associates that these clinical conditions are due to a *circus movement* of the excitation wave. That is to say, the wave starting at one place takes a devious course through the cardiac musculature to reach the point from which it started and re-enter the path which it had previously traversed. The conception of a circus movement of the excitation wave being the cause of flutter

and fibrillation and an understanding of the factors concerned in the production of the movement dates, however, from the work of Mayer. Mayer induced a circus movement in the umbrella of the jelly-fish (Medusa) by creating a local block and applying a stimulus to one side of the blocked region (fig. 89, I, A). The contraction wave which resulted was forced as a result of the block to take a unidirectional course, and after completing the circuit of the disc of tissue returned to the region of the block, which by this time had disappeared. If the tissue from which the wave had been initiated was again excitable, i.e., had passed from the refractory state, the wave circled the ring a second time, then a third time, and so on repeatedly. When, on the other hand, the disc was stimulated in the absence of a block, a contraction wave set out in both directions and the two waves meeting, after having completed half the circumference of the strip, were suppressed at B (fig. 89, II). That is, further progress of the waves was arrested, for each came to a region of tissue which, being occupied by the other wave, was refractory.

FIG. 89. (Modified from Lewis.) Black = contraction wave. Description in text.

Up to this time fibrillation had been believed to be due either (1) to increased excitability of the cardiac musculature which resulted in the suppression of the normal "coordinating mechanism," the fibers contracting independently of one another rather than as an integrated whole (MacWilliam), or (2) to the initiation of multiple discrete impulses scattered throughout the auricular musculature. It has been shown, however, that areas of depressed excitability—*local blocks*—as first suggested by Porter, constitute an essential factor in the production of fibrillation, rather than heightened excitability. Garrey and Mines linked up Mayer's observations upon Medusa with the fibrillation of cardiac muscle. Mines showed that a similar circular motion of the contraction wave could be induced in the cold-blooded heart. Muscular rings cut from the auricles of large rays were employed. Garrey showed that the conception of multiple foci of impulse initiation scattered throughout the muscle was wrong. He found that if a small piece was cut from the fibrillating muscle, the severed piece of tissue at once ceased to fibrillate, though it still remained excitable and capable of contracting when stimulated. If a series of pieces were cut from the main fibrillating mass the latter became

quiescent when it was reduced sufficiently in size. This observer also induced a circulating contraction wave in large ring-shaped strips of muscle cut from turtle's ventricles. He failed to produce a circus movement if the strips were of small diameter.

From these researches it was concluded that four conditions were involved in the establishment of the circus movement:

- (1) Local blocks
- (2) Shortened refractory period
- (3) Slow rate of conduction of the wave
- (4) An annular course of sufficiently large diameter.

A wave having, as a result of local blocks, been deflected into a circular course can continue to cover the same ground over and over again only if a *gap of responsive (non-refractory) tissue exists between the advancing margin (or crest) of the wave and its tail*. As in the experiments of Mayer cited above, a zone of refractory tissue in front of the wave at once arrests its progress. The shorter the refractory period, the slower the transmission rate, or the larger the circular path, the wider will be the gap. So long as the gap is maintained, i.e., so long as the advance and the retreat of the wave proceed at equal rates and the length of the strip remains unchanged, the movement will continue indefinitely. Closure of the gap by altering one or other of the foregoing conditions brings the circus movement to an end.

Flutter or fibrillation can be induced in dogs by stimulating the auricle with electric shocks repeated in rapid succession (usually around 400 per minute for the production of flutter and about 3000 per minute for the production of fibrillation). During the application of the stimulus the auricular muscle responds at a rate corresponding to the frequency of the shocks, and in a successful experiment continues to beat at an abnormally rapid rate after the stimulus has been withdrawn. But the very high rate of beating—1000 to 3000 per minute—is not maintained as an after effect; the rate drops to around 500 or 600 per minute. The direction taken by the excitation wave, during flutter or fibrillation produced in this way, is quite independent of the point to which the stimulus was applied.

Lewis has studied the mechanism in the mammalian auricle during flutter or fibrillation induced by electric stimulation and has come to the conclusion that multiple blocks are created throughout the auricular muscle. According to him the blocks are produced by the *partial refractory state* of the muscle. This (which should not be confused with the relative refractory period) is defined as the state immediately following the passage of the impulse when some fibers are still refractory while others in the immediate neighborhood have recovered from the previous contraction, and are, in consequence, able to respond to the next impulse. When for any reason the heart rate is greatly increased, diastole is shortened to such an extent that the impulses reach the auricular muscle during this critical period of partial refractoriness. Since, of course, the excitation wave can be transmitted only by the responsive fibers,

it is deflected from its normal course and forced to follow a more devious path. It weaves its way sinuously through the muscle, its transmission time from point to point in the auricle being thereby considerably delayed. The conductivity of the responsive fibers is not impaired, but the longer course which the impulse is compelled to take has the same effect in the production of a circus movement as if an actual depression of

FIG. 90. Diagrams showing, A, circus movement in dog's auricle during flutter, and B, normal direction taken by the impulse; S.V.C., superior vena cava; I.V.C., inferior vena cava. The values written on the diagrams are the relative times in seconds at which the excitation was found to reach the points marked by arrow heads. The direction of each arrow head indicates the ascertained general direction taken by the excitation wave in passing that particular point. (After Lewis.)

conductivity existed. The lengthening of the transmission time combined with the shortening of the refractory period of the muscle, which automatically supervenes when the cardiac rate becomes very rapid, permits the impulse to continue its circular course upon reaching the point from which it started. The final condition, however, must be present, namely, a ring of tissue sufficiently large in diameter to permit a proportion of the fibers to become responsive before the contraction wave again reaches them. On the other hand,

if flutter or fibrillation exists either of the following changes will tend to close the gap between the head and the tail of the revolving wave and bring the circus movement to an end.

- (1) Lengthening of the refractory period.
- (2) Shortening of the transmission time, either by increasing the conductivity of the muscle or through the transference of the excitation wave to a smaller ring of tissue.

THE LOCATION OF THE CIRCULAR PATH TAKEN BY THE IMPULSE. The impulse is believed to travel in those natural rings of muscle encircling the openings of the great veins. Lewis has mapped out the course taken by the excitation wave during experimental flutter; contacts were placed upon the auricular muscle and the times of arrival of the wave at different points recorded. In many instances it was found to travel in the right auricle from below the inferior vena cava, up the taenia terminalis and around the superior vena cava, thus following an annular course which included both caval orifices (fig. 90, A). This route is, of course, quite different from that which the wave normally follows (fig. 90, B). The course taken by the excitation wave is not dependent upon the point of stimulation; it follows the same course whether the auricular muscle is stimulated in the region of the appendix, near the inferior vena cava or elsewhere.

The *circular* (really elliptical) or *mother wave* is the governing factor in the flutter rhythm, from it *centrifugal waves* are thrown off, like sparks from a Catherine wheel, which travel through the auricular musculature and die away in the outlying regions, e.g., right and left appendices and the sleeves of the great veins.

There seems to be little doubt that clinical flutter, like the experimental condition, is due to a circus movement. Further evidence for this view was afforded by a study of the movements of the electrical axis (see p. 184) in patients suffering from the disorder. Simultaneous records were taken from three leads represented as shown in figure 91, by lines joining a point near the manubrium sterni, the ensiform cartilage and the seventh dorsal spine. These form an equilateral triangle embracing the base of the heart. The direction of the electrical axis was determined at $\frac{1}{10}$ second intervals. As shown in the figure the axis was found to rotate anti-clockwise through an angle of 360° .

Flutter and fibrillation are now considered to be essentially the same nature. Impure flutter is a transition stage between pure flutter and auricular fibrillation in nature. In pure flutter the central or mother wave is repeated over and over again with precise accuracy. It and the centrifugal waves pursue their prescribed courses uniformly from cycle to cycle. In impure flutter the irregularity is accounted for by the greater degree of deflection of the centrifugal waves. This is brought about supposedly through an increase in the partial refractory state, i.e., more unresponsive fibers are thrown in the path of the waves in their passage through the eccentric regions of the musculature; it

is to be expected that when waves are forced to pick a very devious way through the muscle their course will not be repeated faithfully from cycle to cycle. The path of the central wave is thought, however, to be disturbed relatively little.

In fibrillation, though the general revolving movement of the mother wave is still maintained it is not believed to follow precisely the same course from cycle to cycle as it does in flutter.

The theory of circus movement as outlined is very widely though not universally accepted. Brams and Katz believe that if a circus movement is responsible for flutter and fibrillation more than one circulating wave must exist. They base this conclusion upon the

fects will tend to close the gap and slow the auricular rate. (3) It slows conduction through the junctional tissue. The vagal effect (1) is therefore opposed to the direct effect upon the auricular muscle. (2) The former usually overbalances the latter, with the consequence that when the drug is given in auricular fibrillation the auricular rate is slightly increased. By slowing A-V conduction (3), however, the drug serves to block impulses passing to the ventricle, and so permits fewer impulses from the auricle to reach the lower chambers. The ventricular rate is therefore slowed and rendered more regular. When given in flutter the drug brings on auricular fibrillation. This effect is probably due to the vagal effect of the drug in increasing the transmission rate, and so of speeding up the revolutions of the wave. When the drug is discontinued the fibrillation frequently ceases, to be replaced by the normal rhythm. This action of the drug is made use of in the treatment of flutter; the conversion of the latter into fibrillation is aimed at deliberately. Digitalis, according to Gold and Cattell also acts directly upon the ventricular muscle fibers in heart failure, increasing the force of contraction.

QUINIDINE (an isomer of quinine) also exerts a three-fold action in fibrillation. (1) It depresses or abolishes vagal tone and so lengthens the refractory period of the auricular muscle and decreases the transmission rate. This action upon the vagus is therefore opposite to that of digitalis. (2) It acts directly upon the auricular and ventricular muscle, lengthening the refractory period (by from 50 to 100 per cent) and slowing the transmission rate. (3) It depresses conduction in the junctional tissues. Its action upon the junctional tissue will, like digitalis, protect the ventricle from the rapid rhythm of the auricle. The lengthening of the refractory period of the auricular muscle tends to close the gap between the crest and tail of the circulating wave and so to bring the circus movement to an end. The prolongation of the transmission rate will, of course, have the opposite effect namely, to widen the gap, but the former action usually prevails and the circus movement is abolished, the normal auricular rhythm being restored in about 60 per cent of cases of auricular fibrillation. When the refractory period and the transmission rate are lengthened equally the circus movement obviously will persist (gap not changed) but the auricular rate is reduced (the wave revolves more slowly). Quinidine thus differs in action from digitalis which does not abolish the fibrillation of the auricle or reduce its rate of beating. In the restoration of the normal auricular rhythm by quinidine fibrillation is frequently converted first to flutter.

The different effects of quinidine upon the heart interact in a complicated manner. For example, its action upon the ventricular rate will be the resultant of the following three effects.

(1) Rapid auricular beating tends automatically to depress conduction through the A-V connections. Therefore when the rate of the auricle is reduced by the drug, A-V conduction is increased.

(2) The reduction in vagal tone also increases A-V conduction.

(3) The direct effect of the drug upon A-V conduction, as stated above, is one of depression.

As a matter of fact (1) and (2) frequently overbalance the last effect (3) and some increase in the ventricular rate results.

Quinidine in overdosage produces severe toxic effects among which are auriculo-ventricular block, extrasystoles, paroxysmal tachycardia, and even death as a result of ventricular fibrillation. This latter effect of the drug, it has been suggested, is due to its setting up a circus movement in the ventricle, as a result of its greater effect in reducing the rate of conduction in the ventricular muscle than in lengthening the refractory period. The return of the normal auricular contractions under quinidine treatment is sometimes, though rarely, followed by the dislocation of an intra-auricular thrombus and death from embolism. Complete standstill of the heart has also been reported as a result of the

FIG. 92. Radial tracing showing pulsus alternans (after Mackenzie).

paralysis by the drug of the sino-auricular and auriculo-ventricular nodes and other tissues capable of impulse initiation.

C. ALTERNATION OF THE HEART. PULSUS ALTERNANS

This is a condition in which every second wave in a pulse tracing is of relatively small amplitude. This peculiarity of the arterial pulse is due to alternate variations in the strength of the ventricular systoles, and to a smaller quantity of blood being ejected into the aorta during the weaker beat. Figure 92 shows a typical sphygmogram of this condition. There is as a rule little or no difference in the lengths of the intervals between pulse beats. When a slight difference does exist, the interval succeeding the strong beat is then longer than that following the weak beat. It will be remembered that in the bigeminal pulse, which might in some instances be confused with alternation, there is inequality in cycle lengths (p. 196), but the longer interval follows the *weak* (premature) beat. Furthermore, in alternation the

ventricular rhythm does not share, or does so very rarely, in any irregularity of the pulse intervals which may occur in the arterial tracing. The electrocardiogram, for instance, shows no discrepancies in the length of the intervals between the R waves. The slight variations in the pulse intervals are attributed by Lewis to a slower rate of transmission of the weaker pulses to the periphery. When records are taken simultaneously of the apex and the arterial pulse, it is sometimes found that the weak beats of the former coincide with the strong beats of the latter. This discordance between apex and arterial beats is explained

alternation may occur without alternation of the pulse.

It is not possible to detect *pulsus alternans* by palpation of the pulse, the variations in strength of the pulse beat being too slight to be perceptible, but it is clearly revealed in the sphygmogram (fig. 92). It may also be detected by means of a blood pressure armlet. The pressure in the armlet is raised gradually, when it is found that at a certain level the weaker beats are suppressed, but the stronger beats get through. The pulse at the wrist is then precisely half the ordinary rate. The pressure during the weaker beats may be as much

FIG. 93. I, sinus arrhythmia; II, sinus bradycardia; III, sino-auricular block. (Kindness of Dr. John Hepburn.)

upon the assumption that those muscle fibers which contract during the weak apical impulses though less numerous are actually more effective in ejecting the blood than those causing the stronger thrusts at the apex. (See, Theory of Alternation, below.) The appearance of alternation in the electrocardiogram (e.g., alternate variations in the height of the R wave) is rare. When this so-called *electrical alternation* does occur the larger deflections sometimes correspond to the weaker pulse beats. But, it will be recalled in this connection that the deflections of the electrocardiogram are determined by the balance of the electrical forces developed during the cardiac contraction rather than upon their total value. Electrical

as 25 mm. Hg below that during the stronger, but usually the pressure difference is not more than 5 or 10 mm. Persistent alternation of the heart when the pulse is slow or of normal frequency is usually indicative of grave disease of the myocardium. Alternation sometimes also occurs at rapid rates of beating, e.g., auricular fibrillation, paroxysmal tachycardia etc., but it is then of less serious significance.

THEORY OF ALTERNATION. The "all or none" law states that the cardiac muscle responds maximally to any stimulus that is capable at all of evoking a response. It is apparently difficult to reconcile this principle with the varying force of the ventricular contractions in alternation, unless it be assumed that during the weak

beat, a smaller proportion of the heart fibers respond than during the strong beat. This is the prevailing view.

The heart, it is thought, must be in what has been called a *hypodynamic* state in order for alternation to occur. That is, the heart muscle is so depressed that only half of its fibers have recovered from the previous contraction before the impulse arrives. These fibers alone contract, and when the next impulse arrives they are still refractory, but those which had not previously contracted have recovered their irritability and now respond. In this condition all beats are weak but equal. Should a ventricular extrasystole occur in such a heart, the long pause which follows shifts the balance between the refractory and the non-refractory fibers and precipitates the alternating rhythm. After the long pause of the premature beat a larger proportion of fibers have had time to recover and are therefore able to respond to the impulse. The next impulse, however, finds the muscle in a partial refractory state, i.e., only a small proportion of the fibers have by this time recovered. They only can respond—a weak beat results. This small proportion of fibers when the next impulse arrives will in turn be refractory, but the larger proportion which had not previously contracted will now respond—a strong beat results. So the alternating rhythm is perpetuated, the fibers which responded during one contraction fail to contract at the next beat and conversely those which had failed to respond to one impulse respond to the next.

D. IRREGULARITIES DUE TO VARIATIONS IN VAGAL TONE

1. SINUS ARRHYTHMIA (fig. 93, I)

This is a condition in which rhythmical variations in the rate of the whole heart occur synchronously with respiration. It is due to alterations in the strength of the vagal influence upon the pacemaker (S-A node) as

a result of the respiratory excursions, the heart rate increasing toward the end of inspiration and slowing toward the end of expiration. It is a youthful irregularity, being very common in children, and may be considered a physiological phenomenon. That it is entirely of vagal origin is shown by the fact that it is abolished by atropine. It also disappears when the heart rate increases as a result of exercise, fever, etc., but is enhanced by deep breathing.

II. PHASIC IRREGULARITY

In this disorder periodic slowing of the heart occurs for a few seconds quite independently of the respirations. It also is a vagal effect since it is abolished by atropine. The manner of its production is unknown. It occurs in convalescence from acute fevers, and sometimes during the administration of digitalis.

III. SINUS BRADYCARDIA (fig. 93, II)

This is a persistent slowing of the whole heart due to increased vagal tone influencing the sino-auricular node. The rate may be as slow as 40 per minute. Bradycardia of this nature occurs in apparently healthy persons, many of whom are athletes.

IV. SINO-AURICULAR BLOCK (fig. 93, III)

The entire heart (auricles and ventricles) misses a beat at regular or irregular intervals. The condition thus differs from A-V block in which only the ventricle misses (p. 190). A complete set of waves is therefore dropped from the venous or electrocardiographic tracing, and the arterial pulse intermits. Since the condition is temporarily abolished by atropine and may be induced by stimulation of the vagus, it is probable that the missed beats are due to the action of the nerve upon the S-A node. Sino-auricular block sometimes results from digitalis administration.

CHAPTER XXV

THE REGULATION OF THE HEART'S ACTION

THE HEART RATE

In general, the rate of the heart bears an inverse relationship to the size of the animal, and a direct relationship to the metabolic rate. The heart rate in the canary, for example, is in the neighborhood of 1000 beats per minute, whereas that of the elephant is about 25. The average rate in adult man is around 70 per minute, but there is a rather wide variation between individuals, a rate considerably below or above this average being not uncommon. Muscular training tends to reduce the cardiac rate; athletes not infrequently having a pulse rate between 50 and 60. On the other hand, a rate between 80 and 90 is sometimes seen in other healthy persons. The rate diminishes progressively from birth, when it is around 130 per minute, to adolescence, but increases slightly again in old age. Among physiological conditions which temporarily increase the heart rate are, *muscular exercise* (p. 210), *emotional excitement* and *high environmental temperature*. It also increases during *digestion*. The rate is lowered during *sleep* (55 to 60). Among pathological conditions which cause an increase in cardiac rate are *hemorrhage*, *surgical shock*, *hyperthyroidism*, *fever* and certain *cardiac arrhythmias*, e.g., paroxysmal tachycardia (p. 196), auricular fibrillation, etc.

Tachycardia and *bradycardia* are general terms used to denote, respectively, any considerable increase in heart rate above, or reduction below, the normal average.

Cardiac behavior is influenced by three agencies, I, *nerves*, II, *chemical materials*,—hormones, metabolites and inorganic salts in the blood. III, *mechanical effects* exerted upon the muscle fiber itself by the blood within the heart chambers. Each of these will be considered separately.

I. NERVOUS CONTROL OF THE HEART

The heart, as we know, beats rhythmically after its complete separation from the central nervous system (p. 156) but in the intact animal this automatic action is under the continuous influence of nervous impulses. The nervous mechanism comprises groups of nerve cells in the medulla—the *cardiac centers*; various *afferent pathways* along which impulses are conveyed to

these centers from numerous regions of the body; and the *vagus* and *accelerator* or *augmentor* nerves which transmit impulses from the centers to the heart.

THE VAGUS NERVES

The vagus nerves are cardio-inhibitory. This action was discovered by the Weber brothers in 1845. They convey fibers, belonging to the parasympathetic division of the involuntary nervous system, from a center in the medulla (*cardio-inhibitory center*) to the special tissues of the heart. The medullary center was located by Miller and Bowman in the dorsal nucleus of the vagus situated in the floor of the 4th ventricle. Weak electrical stimulation of this area produced slowing of the beat, and stronger currents complete arrest of the heart. The cardiac fibers of the vagus separate from the trunk of the nerve in the neck between the origins of its superior and inferior laryngeal branches. Intermingling with fibers of the accelerator nerves they enter into the formation of the deep and superficial cardiac plexuses whence they are continued to the heart.

Fibers derived from the *right nerve* terminate around ganglion cells in auricular tissue in the immediate neighborhood of the sino-auricular node (p. 163). These cells serve as relay stations in the transmission of the vagal influence; their axons enter the node and are disposed in a plexiform manner around groups of muscle cells in the nodal tissues. The *left nerve* establishes similar relationships with the auriculo-ventricular node. Its terminations arborize around ganglion cells in the interauricular septum which in turn send axons to the muscular elements of the nodal tissue. The connections of the two nerves are not, however, confined to the respective nodes, for though the right nerve is chiefly distributed to the sino-auricular and the left to the auriculo-ventricular node, each node also receives some filaments from the opposite nerve.

Stimulation of the cardiac vagus causes pronounced slowing or complete stoppage of the heart and, in consequence, a fall in blood pressure (fig. 94). The slowing is brought about mainly through the lengthening of diastole, the duration of systole being relatively little affected. When the heart

ceases to beat it does so in the diastolic phase of the cycle, appearing fully relaxed and engorged with blood. For these reasons the vagi are sometimes referred to as the diastolic nerves. The vagal effect upon the heart thus resembles the action of an excess of potassium (potassium inhibition, p. 158).

When complete stoppage of the heart is caused by vagal excitation the ventricles, but usually not the auricles, commence after a time to beat again, though the stimulation of the nerve is continued. This is spoken of as the "*escape of the heart*" from the inhibitory influence. The amplitude of the returning contractions is frequently greater than usual. The escape phenomenon cannot be explained with entire satisfaction; it is not due simply to fatigue of the nerve and its failure to transmit impulses. The distension of the cardiac

order to evoke a response from the auricle a stronger stimulus must be applied to the muscle during vagal stimulation than at other times. The slowing, or stoppage of the ventricular beat is an indirect effect due to auricular slowing, or arrest of the auricular contractions; or to depression of conduction in the auriculo-ventricular connections. That is, in the latter instance, partial or complete heart block is temporarily induced. If the A-V bundle is severed vagal stimulation is then without effect upon the ventricular rate.

The effect of vagal stimulation upon the auricular rate is ascribed by Eyster and Meek to a shift of the pacemaker to a less rhythmical region, that is, to the production of a block in the upper part of the S-A node, or, with stronger stimulation, to complete suppression of impulse formation in this region. The duty of initiating the impulses devolves then upon regions, e.g., the lower part of the S-A node, the A-V node, or other parts of the special tissues possessing lower rhythmical powers. Evidence for this view is afforded by the observation that shortening of A-V intervals or the development of nodal rhythm (see p. 194) may result from vagal stimulation. It has also been shown that primary negativity can no longer be located in the upper part of the sino-auricular node (p. 163) when the vagus (right) is strongly stimulated but is found to have descended to the lower part of the S-A node or to the A-V node. Potassium salts also cause a shift of the region of primary negativity from the upper to the lower part of the S-A node—another example of the similarity between vagal and potassium inhibition. Potassium also depresses auriculo-ventricular conduction.

The right and left vagus nerves differ in their effects. Stimulation of the right nerve which, as already mentioned, terminates chiefly in the S-A node, results mainly in slowing and weakening of the auricular beat, and, as a secondary result of this, in reduction of the ventricular rate. Excitation of the left nerve which ends chiefly in the A-V node causes ventricular slowing or stoppage, by depressing A-V conduction and blocking the auricular impulses; little effect upon the auricular rate results. An electrocardiogram, for example, taken during stimulation of the left nerve shows a greater number of P (auricular) than of R (ventricular) deflections.

The difference between the effects of the two nerves varies considerably in different species. For example, the left nerve in the tortoise depresses conduction from

FIG. 94. Showing the effect of vagal stimulation upon the arterial blood pressure. Note that although stimulation was continued, escape occurred, which in this instance was confined to the ventricles (McDowall).

chambers (lengthening of muscle fibers, p. 216) by the blood accumulated during the period of cardiac quiescence is probably a factor. There is some evidence that acceleration of acetylcholine destruction is concerned in the escape mechanism. Nahum and Hoff found that the escape phenomenon is greatly diminished after adrenalectomy and excision of the stellate ganglia, and conclude that adrenaline and the sympathetic nerves play an essential rôle in its production. The impulses which re-start the heart apparently arise from some level in the junctional tissue below the level of the S-A node.

In mammals the vagus nerves exert their effects upon the heart through their action upon the auricular muscle and the junctional tissues. They exert no direct action upon the ventricular muscle. The auricular effects are, *slowing* and *strengthening* of the beat, and *shortening of the refractory period*. *Irritability* of the muscle is also depressed, i.e., in

auricle to ventricle but exerts no effect upon the auricular rate, while slowing of the auricular rate is the sole result following stimulation of the nerve of the right side. In the dog similar differences have been demonstrated. Nevertheless, in the latter animal and in other mammals the right nerve depresses conduction to a greater degree than has been supposed, its effect being merely masked by the greater effect which this nerve, as compared with that of the left side, exerts upon the auricular rate. Increase in heart rate automatically depresses A-V conduction; consequently when the right nerve is stimulated the slower rate which results induces an improvement in conduction which will offset any direct depressing effect of this nerve upon the A-V tissues. Lewis and Cohn found that when arrangements were made to maintain the auricular rate constant during stimulation of the right vagus, the effect upon conduction was only slightly less than that shown by the left nerve.

When the auricular beat is abnormally rapid as a result of a circus movement (p. 201) vagal stimulation increases the rate at which the impulse is transmitted through the auricle. This effect, however, is not the result of any favorable influence which the nerve exerts upon the fundamental property of muscle-fiber conduction, but is due rather to the shortening of auricular systole and, in consequence, of the refractory period of the muscle. The state of partial refractoriness which the rapid beating had induced is lessened. This enables the impulse to take a shorter course which in turn causes a still more rapid fibrillating rate (up to 3000 per minute). This effect of stimulation of the vagus in the conditions of flutter and fibrillation has been termed *rapid re-excitation*. The phenomenon is demonstrable in experimental flutter either by direct stimulation of the nerve or by the administration of a vagotropic drug such as pilocarpine. It is possible that it occurs occasionally as a temporary manifestation in clinical flutter or fibrillation. The effect of vagal stimulation upon the A-V connections during flutter or fibrillation is, as in the normal heart, to depress conduction and slow the ventricular rate.

The tone of the vagus

During the normal life of the animal the vagus nerves exert a continuous restraint upon the action of the heart. In other words, the vagus or rather, the cardio-inhibitory center, possesses tone, impulses passing from it in a continuous stream to the heart. This effect, which may be compared to the action of a dragging brake, can be readily demonstrated in animals by cutting or freezing the nerves. The heart's action then immediately becomes greatly accelerated. The increase in rate following the removal of the vagal influence also occurs though the stellate ganglia (p. 938) have been previously excised; the result therefore

cannot be due to an increased action of the accelerator nerves. The tonic action of the vagus nerves may be annulled by means of atropine, $\frac{1}{16}$ to $\frac{1}{8}$ grain being required in man to completely abolish their effects, the heart rate then increasing to 150 or 180 per minute. The difference between this rate and the normal resting rate of 70 per minute, therefore, represents the vagal effect which is being constantly exerted under ordinary circumstances. Various conditions, physiological and pathological, alter the tone of the vagus center. The tone is naturally higher in some species, e.g., the dog, which is capable of feats of endurance, than in others, e.g., the domestic rabbit. It also shows individual variations in man, athletes usually showing a higher tone than those who lead sedentary lives.

Vagal tone is apparently reflex in nature and dependent upon afferent impulses flowing to the vagus center especially along the sinus and aortic nerves (p. 241, 242). Section of these nerves causes an increase in heart rate and little further acceleration occurs as a rule when the vagi themselves are subsequently severed.

THE ACCELERATOR OR AUGMENTOR NERVES

The accelerator fibers were described by Von Bezold in 1863. They belong to the thoracolumbar division of the involuntary nervous system and arise from cells situated in the lateral horns of the upper thoracic segments of the spinal cord—I to V T (see p. 940). These cells constitute a spinal cardio-accelerator center. The preganglionic fibers enter the gangliated cord of the sympathetic to connect with cells in the *inferior, middle and superior cervical ganglia*. In many animals and also often in the human subject the inferior cervical and the first thoracic ganglia are fused into an irregularly shaped structure called the *stellate ganglion* from which accelerator fibers pass directly to the heart. The heart also receives accelerator fibers *directly* from the sympathetic chain as far down as the 4th or 5th thoracic ganglion. In order, therefore, to remove all accelerator influence from the heart it is necessary, as shown by Cannon, Lewis and Britton, to interrupt these connections as well as to remove the stellate ganglia. The axons of the cells of the cervical ganglia (postganglionic fibers) form the *inferior, middle and superior cardiac nerves* (fig. 95). The post-ganglionic fibers, especially those forming the nerves of the right side, terminate in the sino-auricular node. Those of the left side are

distributed mainly to the AV node and bundle. According to Nonidez, the sympathetic efferent fibers which reach the heart are contained mainly in the middle cardiac nerve. The superior cardiac nerve is distributed to the large arteries while the inferior cardiac nerve is mainly afferent. The spinal accelerator center is subordinate to higher centers. The precise locations of the latter are not known, but the experiments of Beattie, Brow and Long indicate the presence of a center in the posterior hypothalamic region (p. 883); and Green and Hoff observed changes in heart rate, in blood pressure and in limb and kidney volumes upon stimulating the cerebral cortex (motor and

prone, during chloroform anesthesia, to induce fibrillation of the ventricles (p. 198). The increase in the ventricular rate that occurs when these nerves are stimulated is accomplished usually through the shortening of both systolic and diastolic periods, but systole is curtailed to a greater degree than diastole, so that the ratio of the length of systole to the length of the entire cardiac cycle

$\left(\frac{\text{systole}}{\text{cycle length}} \text{ ratio} \right)$ is decreased.

There is evidence that the effect of the accelerators upon A-V conduction is, as one would expect, opposite to that exerted by the vagus.

Accelerator tone

The accelerators also exert a tonic action. This may be demonstrated by excision of the stellate ganglia when the heart rate slows. Gasser and Meek, for example, found that when the ganglia were removed but the vagi left intact an immediate and marked fall in rate (about 40 per cent) occurred; further slowing occurred later which was attributed to a rise in vagal tone. Slowing of the rate is produced, however, by excision of the ganglia, even though vagotomy has been performed previously; this fact of course precludes the possibility of the immediate reduction in rate following excision of the stellate ganglia being due to increased vagal tone.

Bronk and his associates have demonstrated the existence of accelerator tone in the cat by recording the action potentials from nerves leaving the stellate ganglion. A fairly continuous discharge of impulses at a rate of from 5 to 20 per second was observed. Stimulation of the central end of an afferent nerve (e.g., sinus or aortic nerve) caused a discharge of impulses in the efferent fibers at the frequencies of the afferent impulses.

CARDIAC REFLEXES

Under ordinary conditions, the activities of the cardio-inhibitory and cardio-accelerator centers which result in the continuous discharge of impulses along the corresponding cardiac nerves are in turn dependent to a very large extent, if not entirely, upon the reception of impulses by afferent paths. In other words, the maintenance of the tone of the centers, and so of the normal resting rate of the heart, and the alterations in rate which occur under various physiological conditions are in large measure either reflex in nature or due to impulses received from cerebral centers. The impulses which stream into the nervous centers

FIG. 95. Diagram of the cardiac nerves. Broken lines = preganglionic sympathetic fibers.

premotor areas) in cats and monkeys. A medullary center also probably exists.

Stimulation of the accelerators causes quickening of the rate of both auricles and ventricles and an increase in the force of the contractions. We have seen that the vagus exerts its influence chiefly upon the auricle and junctional tissue, affecting the activity of the ventricle only indirectly. The accelerator nerves, on the other hand, exert, as well, a direct action upon the ventricular muscle. Stimulation of the accelerator nerves may so excite the ventricles as to induce fibrillation. Fibrillation of the auricles, on the other hand, is not induced by this means. We have also seen that adrenaline (which has an action upon the heart similar to that following stimulation of the accelerators) is particularly

arise in all parts of the body, the heart itself included. By these influences the tone of either center may be exalted or depressed, and corresponding changes produced in the cardiac rate. For example, Goltz showed many years ago that reflex inhibition of the frog's heart could be induced by repeated gentle taps upon the intestines. Reflex slowing of the pulse can usually be demonstrated in the human subject by pressure upon the eyeball at the outer canthus (oculo-cardiac reflex), or by the stimulation of nasal branches of the fifth nerve. Stimulation of afferent fibers in the respiratory passages¹ as by the inhalation of irritating vapors, e.g., anesthetics, is particularly likely to cause reflex inhibition of the heart. Extrasystoles and bradycardia have been demonstrated electrocardiographically in man during abdominal operations, the irregularities being the consequence, apparently, of visceral stimulation. Excitation of the central end of various peripheral nerves, e.g., the sciatic, causes reflex changes in the pulse rate. In these last instances acceleration is more readily obtained than inhibition. The irradiation of impulses on to the cardiac centers from the cerebral centers, e.g., from the motor area at the commencement of muscular exercise (p. 210) or from regions concerned with emotional manifestations, are held responsible for the changes in pulse rate which occur under these conditions.

Afferent endings in the heart and aorta

Afferent fibers are contained in the cardiac vagus itself; the receptors of these lie within the heart tissues, and upon the aortic arch. If, therefore, the cardiac vagus on one side be cut and its central portion (i.e., the end leading to the brain) stimulated, a reflex through the cardio-inhibitory center and the opposite vagus occurs which alters the cardiac rate. The nature of the change in rate—whether acceleration or inhibition—which will result from stimulation of the central end of the vagus or of most other afferent nerves cannot always be foretold. As a general rule, however, stimulation of afferent spinal nerves causes acceleration, and of afferent vagal fibers inhibition. The effect which is obtained depends also to a large extent upon the intensity of the stimulus, strong stimuli being more likely to increase the cardiac rate, weak ones to depress it; it depends

also upon the species, in some animals quickening is more readily obtained than slowing, in others the reverse is true. For this reason it has been thought that the vagus and other nerves contained two types of afferent fiber, each type being responsive to different strengths of stimulation, and each being contained in variable proportions in different nerves as well as in the corresponding nerves of different species.

In some animals the vagus gives off a branch composed entirely of afferent fibers. This nerve terminates in the wall of the aortic arch and in the heart itself. It is known as the *aortic or cardiac depressor nerve* (see p. 241) since when excited it induces cardiac slowing and vasodilatation, and, as a result, a fall in blood pressure.

Marey's law

Marey's law states that the pulse rate is inversely related to the arterial blood pressure—a rise or a fall in pressure causing, respectively, a decrease or an increase in heart rate. These adjustments are subserved by:

- (1) A reflex whose afferent limb is constituted of afferent vagal fibers ending in the aortic arch and heart.
- (2) A reflex in which the *sinus nerve* forms the afferent limb. These mechanisms will be considered in chapter XXVII.

A fall in blood pressure causes an increase in the rate of the heart, however, even after it has been completely denervated; the acceleration is attributed to the liberation of adrenaline.

The Bainbridge reflex

The increase in heart rate induced by a rise in the pressure of blood entering the right auricle is known, after its discoverer, as the Bainbridge reflex. It is carried out presumably through the afferent vagal terminations beneath the endocardium and in the walls of the great veins near their entrance into the auricle. The nerve filaments are stimulated by the increased venous pressure which rises only after the cardiac chambers have been completely filled. Through this mechanism, the heart rate is adjusted automatically to the volume of blood poured into its chambers (the venous inflow).

THE RECIPROCAL ACTIONS OF THE CARDIAC CENTERS

Changes in heart rate are brought about not simply by an increase or a decrease in tone of one or other cardiac center but by reciprocal variations

¹The rabbit's heart is slowed to between 50 and 60 beats per minute by the inhalation of ammonia. By means of this response it is possible to make slowing of the heart a conditioned reflex to the ringing of the bell (see Chapter LXX).

in the tone of both. An increase in heart rate for example is due to a decrease in tone of the cardio-inhibitory center accompanied by an increase in tone of the accelerator center. A decrease in heart rate is the result of increased tone of the cardio-inhibitory center together with reduced tone of the accelerator center. Such a balanced mechanism must make for more rapid, smoother and nicer adjustments of the cardiac rate than would be possible otherwise. Generally speaking, however, changes in tone of the cardio-inhibitory center appear to exert a greater influence than do alterations in accelerator tone. For example, the slowing of the heart which results from a rise in arterial pressure is much less pronounced if impulses from the cardio-inhibitory center have been prevented from reaching the heart by section of the vagi. After removal of the stellate ganglia, on the other hand, the cardiac response to a rise in blood pressure is reduced to a less extent. Also, the increase in cardiac rate which occurs at the commencement of muscular exercise is due to a reduction in vagal tone rather than to an increase in accelerator tone. The reciprocal relationship between the cardiac centers in the reflex acceleration of heart rate resulting from stimulation of the central end of the sciatic nerve has been demonstrated by Hooker and by Bainbridge. Though reduction in vagal tone was the more important factor in the accelerator response, increased tone of the accelerators was also shown. When, for example, the vagi were cut and the heart maintained at a constant rate by stimulation of the peripheral end of one of the cut nerves, or by the administration of pilocarpine, excitation of the central end of the sciatic nerve caused cardiac acceleration. This was attributed to an increase in accelerator tone; adrenaline liberation was not a factor since acceleration occurred after adrenalectomy. More recently, Moore and Cannon have found that after sympathectomy, vagal action is capable of slowing the heart from a rate of 150 beats per minute to 75, and the sympathetic mechanism, after vagotomy, can increase the rate from 125 to 225.

VOLUNTARY ACCELERATION OF THE HEART RATE. Several instances (Taylor and Cameron, and Ogden and Shock) have been reported of individuals possessing the power of voluntarily accelerating the heart rate. In one such case the effect was brought about apparently through the discharge of impulses along accelerator nerves since other sympathetic manifestations, e.g., vasoconstriction, glycosuria and dilatation of the pupils accompanied the increased pulse rate.

THE ACCELERATION OF THE HEART IN MUSCULAR EXERCISE AND IN EMOTIONAL STATES

There are two stages in the cardiac acceleration which accompanies muscular effort, namely, the increase in rate which occurs immediately upon the commencement of the work, and that which develops subsequently and more gradually. The acceleration of the pulse at the outset of the exercise occurs too promptly to be the result of an increased flow of blood from the contracting muscles to the heart (Bainbridge reflex). Miss Buchanan has shown, for example, that with even very light exercise, namely, clenching the fist, the diastolic period *immediately* succeeding the commencement of the movements is shortened. Thus, before the exercise the length of the cardiac cycle was 0.82 second (pulse rate 73). The first cycle after starting the exercise was 0.67 second. Subsequently the cycles shortened progressively to reach a value of 0.56 second; this corresponds to a pulse rate of about 107 per minute. Moreover, it has been shown by other observers that the initial acceleration does not occur if the muscles are moved passively or tetanized by direct stimulation.

The last mentioned observation indicates that the effect is not the result of a reflex elicited through receptors situated in the muscles themselves. It is concluded that the initial acceleration results from impulses arising in the motor areas of the cortex and overflowing on to the cardio-inhibitory center. On the other hand, *if the circulation to the arm or leg is arrested* while the limb muscles are contracting the pulse accelerates and, provided that the limb's circulation remains occluded, the increased rate persists after the exercise has ceased (Alam and Smirk). The effect under such circumstances is evidently due to a reflex from the contracting muscles. Its persistence after cessation of exercise until the circulation is restored and its disappearance thereafter, and also its association with the pain of intermittent claudication (p. 257) strongly suggest that the reflex is initiated from afferent nerve terminals stimulated by metabolites which have accumulated in the contracting muscles. This cardiac reflex, though interesting as a physiological phenomenon is probably of very minor importance in the increased pulse rate in muscular exercise. That depression of vagal tone rather than heightened accelerator tone is the responsible factor is evidenced by the following facts, (a) the shortness of the latent period which is a characteristic of vagal effects, (b) the abbreviation of the cycles through shortening of the diastolic period, which was noted above, is also a criterion of lowered vagal tone (p. 207). Bowen also found that during exercise in man the increase in rate was brought about entirely by short-

ening of diastole. Indeed, systole was actually lengthened at the commencement of the work. Gasser and Meek, experimenting with dogs, found that removal of the stellate ganglia had little or no effect upon the cardiac acceleration occurring early in muscular exercise, whereas this primary increase in rate did not occur after vagotomy. They found, however, that after the initial stages of the work increased accelerator tone contributed as well to the increased frequency. Diastole and systole were both shortened though the vagal effect predominated. The important factor in the delayed effect is no doubt the rise in venous pressure and the elicitation of the Bainbridge reflex (p. 209). Gasser and Meek conclude from their experiments that the chief function of the accelerators is to maintain a steady frequency of the resting pulse and that their influence does not alter to any marked degree under ordinary circumstances, the duty of varying the heart rate devolving chiefly upon the vagal centers. The accelerators provide a factor of safety and, under circumstances of exceptional stress, e.g., strenuous muscular exertion or emotional states, reinforce the vagal effect. The liberation of adrenaline is an additional factor.

It is probable that in such emotional states as fright, anger and mental excitement, the accelerator nerves play a more prominent part in increasing the heart rate than does a reduction in vagal tone. Bond found that sudden startling of an animal, in which adrenaline liberation had been prevented, caused a much greater increase in heart rate if the vagi had been sectioned and the accelerators left intact than in converse experiments (accelerators divided and vagi intact).

THE EFFECT OF DRUGS UPON THE CARDIAC RATE

The efferent vagus pathway, as already mentioned (p. 205), consists of two links—the preganglionic and postganglionic neurons. *Atropine* acts by antagonizing the action of the cholinester which, according to the humoral theory of the transmission of nervous effects, is liberated at the postganglionic terminals. Atropine therefore depresses, or in full doses, completely abolishes vagal action, the effect upon the cardiac rate being the same as if the vagus nerves were cut. *Muscarine*, an alkaloid present in poisonous mushrooms (*Amanita*) has a diametrically opposite effect. Its action upon the cardiac rate imitates that of vagal stimulation, namely, to cause slowing and, finally, complete stoppage of the heart in diastole. The effects of *pilocarpine*, *physostigmine* and the ester of choline, *acetylcholine* (see below) are similar to those of muscarine, causing cardiac slowing or standstill (see also p. 946). Their actions are antagonized by atropine. *Nicotine* first excites the vagus but later acts like atropine, causing vagal paralysis and increased cardiac action. Its site

of action is upon the ganglion cell or at the synapse of the latter with the preganglionic fiber.

THE HUMORAL TRANSMISSION OF VAGAL AND ACCELERATOR EFFECTS

Some few years ago Loewi performed a series of experiments which showed decisively that cardiac inhibition resulting from vagal stimulation is due to the liberation of a chemical substance possessing an action similar to that of *acetylcholine* (see p. 946). It was also shown that the augmentation and increase in heart rate which follow stimulation of the accelerators are due to the action of an *adrenaline-like substance*. His results have been confirmed by others. The experiments were performed as follows. Two frog hearts were perfused with Ringer's solution. One heart (donor heart) was inhibited by vagal stimulation. The perfusion fluid of this heart when perfused through the second heart (recipient heart) caused inhibition of it also. The effect upon the second heart could only have been due to the presence of a chemical material of some sort in the perfusion fluid derived from the first heart; it must have been produced by vagal stimulation. The action of the perfusion fluid upon the recipient heart was annulled by atropine. The cardio-inhibitory action of choline and its ester acetylcholine is also prevented by atropine. The perfusion fluid from a heart during vagal stimulation has been shown, moreover, to cause contraction of the stomach wall of the frog (Brinkman and Van Dam) and of a loop of intestine, effects which are also produced by acetylcholine. The "vagus substance" (Vagusstoff as it was called by Loewi) is also, like acetylcholine, readily destroyed by alkali (or by the esterase mentioned below) but is stable in acid media.¹

The method used by Baingto demonstrate the humoral transmission of vagal effects is shown in figure 96.

It was later demonstrated by Loewi that the heart muscle contained an enzyme—*cholinesterase*—which rapidly hydrolyzed the ester after its liberation into the relatively inactive choline and

¹ Howell was the first to suggest a humoral mechanism underlying the cardio-inhibitory effect. He reported an increase in the concentration of potassium in the fluid perfusing an isolated mammalian heart during vagal stimulation. The resemblance of the action of potassium upon the heart to that produced by stimulation of the vagus has been pointed out on page 206. Howell proposed the theory that the nerve impulses caused the breakdown of some organic compound with the liberation of an inorganic form of potassium (see also p. 949).

acetic acid, and so limited the duration of its action. The action of this esterase is inhibited by physostigmine (eserine). The effect of the latter drug in inhibiting the heart depends solely upon this action. That is, it prevents the hydrolysis of the vagus substance which therefore continues to exert its effect (p. 946).

The liberation of a substance possessing an adrenaline-like action was demonstrated by per-

FIG. 96. The perfusion apparatus A is furnished with an overflow tube B, the height of which can be varied to allow alterations in the perfusion pressure. Fluid is delivered through the tube C. The fluid from A passes through the tube D to the inflow limb E of the double cannula which supplies the donor heart F. After irrigating the interior of the donor heart, the fluid passes by the outflow limb G to the glass cannulated tube H to which is attached the recipient heart I. This cannulated tube is provided with a lateral overflow, so that the pressure of the fluid supplied to the recipient heart remains constant. J and K are the levers to which the hearts F and I are respectively attached (Bain).

fusion experiments of a similar nature. Perfusion fluid collected from one heart during stimulation of the accelerator nerves when perfused through a second heart accelerated its rate.

THE SENSORY NERVES OF THE HEART

The ordinary types of stimulus applied to the heart cause no painful sensation.* The exposed

*This fact was first shown by Harvey upon the exposed heart of the Viscount Montgomery (see p. 514).

heart of a conscious human subject, for example, may be stimulated electrically or mechanically without any sensation of pain being experienced. Pathological processes, especially coronary artery thrombosis and angina pectoris, may, on the other hand, give rise to acute and often agonizing pain (p. 280). The results of experiments upon animals and of operations upon man in which the cardiac sympathetic pathways have been interrupted or blocked by means of alcohol injections, indicate that the route for cardiac pain is solely through sympathetic afferents. The pain fibers are contained mainly in the inferior cardiac nerves but some travel in the middle cardiac nerves. The pain impulses then pass through the corresponding cervical ganglia, and the white rami and posterior roots of the upper four or five thoracic nerves (fig. 95, p. 208). Pain fibers also pass from the heart directly (i.e., not through the middle and inferior cardiac nerves) to the upper four or five thoracic ganglia. Pain and stretch receptors have been described in the cardiac muscle.

II. CHEMICAL CONTROL OF THE HEART. THE INFLUENCE EXERTED UPON THE HEART AND VASCULAR MUSCULATURE BY BLOOD-BORNE SUBSTANCES

The known materials in the circulating blood which influence the action of the heart are, (1) the *mineral constituents*—calcium, potassium and sodium; (2) *adrenaline*; (3) *acid metabolites*—carbon dioxide and lactic acid; and (4) *oxygen*. The specific effects of the inorganic constituents upon the perfused heart have already been considered (p. 157). Their proportions in the general blood stream do not vary under physiological conditions, and rarely, if ever, in pathological states to a sufficient extent to affect materially cardiac behavior. Adrenaline has a very definite action upon the heart and vessels which will be considered in Chapter LIX.

Carbon dioxide and lactic acid

Carbon dioxide exerts an effect upon the cardiac and vasomotor centers and directly upon the cardiovascular musculature. Carbon dioxide and lactic acid, formed during the activity of muscle and other tissues, dilate the peripheral vessels (p. 248). The active tissues are thus supplied more generously with blood. In muscular exercise the greater flow of blood through the muscles causes a greater mass movement of blood along the veins and a greater flow into the cardiac

chambers. The higher carbon dioxide tension in the venous blood coming to the heart from the skeletal muscles enhances the extensibility of the cardiac muscle fiber during diastole and, in consequence, exerts a favorable effect upon the filling of the heart. The cardiac output is therefore increased (pp. 215 and 216).

The junctional tissues are particularly sensitive to high tensions of carbon dioxide, auriculo-ventricular conduction becoming markedly depressed when the carbon dioxide excess is such as to cause a fall in pH of the fluids bathing the cardiac muscle fibers. At a pH of around 7.0 complete heart block occurs. A less pronounced increase in CO₂ tension causes slowing of the heart, as a result of depression of the activity of the sino-auricular node as well as of increased tone of the cardio-inhibitory center. The continued exposure of the heart to a high CO₂ tension causes weakening of the beat and the development of irregular rhythms.

An abnormally low tension of carbon dioxide in the blood is sometimes referred to as *acapnia* (Greek; *a*, privative + *kapnos*, smoke). It occurs in conditions associated with increased pulmonary ventilation, the gas being "pumped" or "blown off" from the body in the expired air. The carbon dioxide deficit produces effects which are the reverse of those caused by carbon dioxide excess. Diastole is incomplete, the tone of the capillaries and small veins is increased (p. 250), the venous pressure falls and the heart chambers are insufficiently supplied with blood. The cardiac output, in consequence, is reduced. Diastole becomes shorter and shorter with a consequent rise in cardiac rate; finally, as Henderson and his associates have shown in animals during prolonged artificial respiration with maximum ventilation, the heart enters into a condition of almost continuous contraction. The blood pressure falls and death occurs from circulatory failure.

Low carbon dioxide tension, if accompanied by a change in blood reaction toward the alkaline side, increases the rate of conduction over the auriculo-ventricular bundle. The rate of impulse initiation in the sino-auricular node is increased; the tone of the cardio-inhibitory center is lowered.

Owing to the several factors involved, the effects of carbon dioxide deficit and carbon dioxide excess upon the action of the heart in the human subject offer many difficulties to the investigator. In forced breathing, for example, the respiratory excursions if violent may interfere with the venous return and reduce the cardiac output. Vincent

and Thompson observed a fall in blood pressure during forced breathing which they attributed chiefly to the mechanical effect of the respiratory movements upon the venous return; they assert that the lowered carbon dioxide tension played a minor rôle. If, on the other hand, the respirations are carried out at a different rate and depth the venous return may be augmented and the cardiac output, in consequence, increased. The effect of forced breathing also varies with the subject and with the type of the breathing, thoracic breathing tending to increase the cardiac output, the abdominal type to reduce it. It is not surprising, therefore, that attempts by different workers to determine the effects of alterations in the carbon dioxide tension of the blood upon cardiac action have given conflicting results. Probably the most complete series of experiments relating to this question have been carried out by Grollman, who employed the acetylene method for the determination of the cardiac output (p. 229). He observed a greater output during forced breathing. The increase he attributed to the rise in metabolism incident to the extra work performed by the respiratory muscles, and to the mechanical effect of the respiratory excursions in augmenting the venous return. For, when the forced breathing was carried out with a *carbon dioxide—air mixture* which maintained the carbon dioxide percentage of the alveolar air around the normal value, an increase in the cardiac output occurred of the same magnitude as that occurring when the over-ventilation was carried out with ordinary air. Breathing a carbon dioxide rich mixture caused no change in cardiac output until the carbon dioxide in the inspired air reached about 6 per cent; then a marked increase in the pulmonary ventilation and a rise in the cardiac output occurred. The latter was attributed also simply to increased respiratory activity.

Grollman concludes that carbon dioxide lack must be of an extreme grade before it exerts an effect upon the output of the heart; in ordinary experiments upon the human subject the loss of carbon dioxide falls short of the point where such an effect is produced. In disease, on the other hand, when a profound lowering of the carbon dioxide content of the blood occurs with a consequent change in the pH of the latter toward the alkaline side, deleterious effects upon the circulation and reduction in the cardiac output would be expected to occur as a result of incomplete diastolic filling. In order to prevent the "washing out" of carbon dioxide during artificial respiration Henderson

advocates the addition of carbon dioxide (7 per cent) to the inspired air.

Oxygen

High tensions of oxygen tend to reduce slightly, and very low tensions to increase the output of the heart. In experiments with subjects who breathed mixtures of oxygen and nitrogen in varying proportions, Grollman found that the cardiac output did not alter until the oxygen content of the mixture had been reduced to 11.6 per cent. A moderate increase in the output then occurred. If the oxygen lack is profound or of long duration the cardiac muscle suffers and the output of the heart then, of course, becomes reduced.

Reduction in the oxygen content of the arterial blood by 50 per cent or more causes a diminution in the amplitude of the T wave of the electrocardiogram. This wave may become flattened out or inverted in all three leads if the anoxemia persists. Changes resembling those caused by coronary infarction (p. 281) may make their appearance. These electrocardiographic effects have been observed in disease and in airmen during ascents to over 5,000 feet.

Breathing a mixture with a very high percentage of oxygen slows the *heart rate*. In the early stages of oxygen lack the heart rate is increased. These effects are brought about presumably through the cardiac centers. In the later stages of anoxemia, heart block, extrasystoles and other cardiac irregularities develop and heart failure supervenes. The inability of the heart muscle to contract any considerable oxygen debt has been mentioned (p. 157).

Asphyxia

The combined effects of oxygen lack and carbon dioxide excess upon the heart rate are seen in asphyxia. At first, marked slowing occurs which is largely a secondary effect of the rise in blood pressure (Marey's law, p. 209) induced through the action of carbon dioxide excess and oxygen lack upon the vasomotor center (p. 248). Later, as the strength of the cardiac muscle weakens the blood pressure falls; the heart rate rises and finally cardiac irregularities appear. It has been shown by McDowall that mild asphyxia exerts a delayed effect upon the cardio-inhibitory center. If an animal is asphyxiated for a short time, cardiac slowing occurs after recovery. During the asphyxial period itself slight cardiac acceleration may occur. The delayed effect is considered to be in the nature of an after discharge (p. 814)

of the cardio-inhibitory center. From this observation it is suggested that the mild asphyxia which accompanies muscular exercise may be a factor in the development of the high vagal tone and slow heart rate found in athletes and others who are accustomed to perform heavy muscular work.

III. THE MECHANICAL FACTORS CONCERNED IN THE REGULATION OF CARDIAC ACTION

The effects of mechanical or physical factors, e.g., venous inflow and arterial blood pressure, upon cardiac behavior have been studied in great detail by Starling and his associates. The experiments were carried out upon the heart-lung preparation of the dog. A description of the preparation follows.

The heart-lung preparation

This method enables the output of the left ventricle to be determined at the same time that any one of several factors, e.g., arterial resistance, venous inflow or temperature, is varied as desired, while the remaining factors are rigidly controlled. The following description is taken in the main from Knowlton and Starling's paper (see fig. 97). The chest is opened and artificial respiration instituted. The arteries arising from the aortic arch are ligated, as well as the azygos vein. Cannulae are tied into the innominate artery (C.A.) and the superior vena cava (S.V.C.). The descending aorta is ligated. Blood which has been defibrinated or rendered incoagulable by the addition of heparin is placed in the reservoir F; this is connected by tubing of wide caliber with the cannula in the superior vena cava. The blood is warmed in its passage through a worm immersed in a water bath. The only channel open to the blood from the left heart is through the innominate cannula. The lesser circulation is undisturbed, the blood from the right heart is oxygenated by passing through the lungs to the left auricle. For the sake of simplicity the pulmonary circulation is not shown in the figure. The innominate cannula connects by one limb of a T-tube with a mercurial manometer M¹. The other limb of the T is connected by tubing with a second T-branch, v, the limbs of which are connected respectively with the resistance R, consisting of a rubber finger-stall enclosed in a sealed tube, T, and the inverted test-tube, B. The air in the latter, since it undergoes compression and decompression with the pulsatile variations in arterial pressure, acts like the air cushion in the stand-pipe of a water system, and serves in lieu of the elastic arterial wall (p. 122). The resistance of the flow of blood through R can be raised to any desired height by means of the bulb S and the pressure bottle A. The pressure exerted upon the collapsible finger-stall is measured by the manometer M². The blood after passing through the peripheral resistance collects in the tube N which is provided with a siphon tube Sy. This

total output of the left ventricle remained practically unchanged though the arterial pressure was raised over 100 per cent (table 17).

It is quite evident from table 17 that the heart responded to a greater venous inflow by increasing its output per beat and not by increasing its rate. It is also true that, if the venous inflow is inadequate, i.e., the heart chambers are not completely filled at the end of diastole, or are just filled and no more, simply increasing the frequency of beat, as by raising the temperature, fails to increase the output. This is obvious, since if the beats have been occurring at the end of a period of rapid filling and no increase in venous inflow occurs as the rate increases, the acceleration in heart rate must be accompanied by a proportional reduction in the volume of blood ejected per beat. The reduction in stroke volume with rise in rate is shown in table

more completely. In moderate exercise, in man, for example, the diastolic size of the heart as observed radioscopically may not increase, whereas the systolic size is less than that during rest.

The experiments of Starling and his colleagues have shown that the dog's heart is capable of pumping in the neighborhood of 57 times its own weight of blood per minute for a considerable length of time. In one instance a heart weighing 42 grams gave an output of 2400 cc. per minute. If the power of the human heart may be taken to be equally great in proportion to its weight, then a heart weighing 300 grams or so should be capable of an output of over 17 liters per minute. The maximal output actually observed in man by indirect methods is more than double this figure (p. 225).

TABLE 18

Dog. 8.5 kilos. Weight of heart 77.5 gm. Small constant venous inflow, heart rate increased. The output remains unchanged
(Markwalder and Starling)

TIME	TEMPER- ATURE	RATE OF HEART PER MINUTE	ARTERIAL PRESSURE	SYSTEMIC OUTPUT	CORONARY SINUS OUTPUT	TOTAL CORONARY OUTPUT (CALCULATED)	TOTAL OUTPUT (CALCULATED)	OUTPUT PER HEART BEAT	VENOUS PRESSURE
	°C		mm. Hg	cc. per minute	cc. per minute	cc.	cc.	cc.	cm. H ₂ O
2:20	28.2	72	119	612	24.20	40.3	652.3	9.05	11.0
2:28	30.2	90	119	612	20.62	34.4	646.4	7.20	9.0
2:37	33.4	114	119	612	18.46	30.8	642.8	5.63	6.2

2:50	37.0	144	117	612	21.20	35.3	647.3	4.47	4.2
2:58	39.0	156	116	612	22.90	38.1	650.1	4.16	3.8

18. If, on the other hand, the venous inflow is large, the heart fills earlier in diastole and a period of diastasis (p. 173) is created. Then any increase in rate by abolishing or reducing this period must increase the output (see also p. 224).

Referring again to table 16 in which it is seen that the increased output is unaccompanied by a notable acceleration of the heart, it must be remembered that the experiments were carried out upon a denervated heart-lung preparation; the Bainbridge reflex (p. 210) was in consequence abolished. It cannot be concluded therefore that in the intact animal the rise in venous pressure which resulted from the greater inflow would not have caused an increase in the rate of the heart. In the intact animal a moderate increase in the output may also be brought about without an increase in the diastolic volume, the ventricles simply emptying

THE SOURCE OF THE ENERGY WHICH ENABLES THE HEART TO INCREASE ITS OUTPUT. THE LAW OF THE HEART

It is well known that skeletal muscle contracts more forcibly if it is loaded by a weight before it is excited. The weight stretches the muscle fibers, i.e., it increases their length and exerts a certain tension upon them. If the muscle is made to contract isometrically the tension developed during the contraction is found to be proportional to the length of the muscle before excitation. The latter is called the *initial length* of the muscle. The tension which the load exerts upon the fibers just prior to their contraction is spoken of as the *initial tension*. The tension developed when the muscle contracts—isometrically—will be referred to as the *developed tension* which, of course, is a measure of

the force of the contraction. When a resting muscle is weighted, little change in initial tension actually occurs until it is extended beyond a length corresponding to that which it possesses when in its natural position in the body, i.e., at its physiological length. Up to this point the developed tension increases with each increment in initial length, but beyond it the developed tension actually becomes less with increasing initial length. Yet, it is only when the muscle is stretched beyond its physiological length that any marked increase in initial tension occurs. The power of contraction of a skeletal muscle is therefore dependent upon initial length and not upon any stimulating effect exerted upon the muscle fibers by initial tension. The relationships between the initial length, initial tension and the developed tension of skeletal muscle during its contraction are shown in figure 98a.

There has been some controversy as to whether the energy liberated by the cardiac muscle is, like skeletal muscle, dependent mainly upon initial length or upon initial tension. The experiments of Starling and his colleagues indicate that initial length is the sole determining factor.

Clearly, there are no means, as in the case of skeletal muscle, by which the length and tension of the cardiac muscle during its relaxation (diastole) or the tension developed during contraction (systole) can be measured *directly*. Yet, the diastolic volume depends upon fiber length (initial length): the intraventricular pressure during diastole represents initial tension, and the pressure developed during systole is related to the tension set up by the contracting fibers (developed tension). When, therefore, simultaneous records of diastolic volume and intraventricular pressures (p. 173) during diastole and systole are secured, the data may be plotted as shown in the diagram (fig. 98b) with volume (cc.) representing initial length, along the ordinates and pressure (mm. Hg) representing tension, along the abscissae. The venous pressure which stretches the cardiac muscle during diastole corresponds to the weight applied to the skeletal muscle. The opening of the semilunar valves against the aortic pressure represents the load against which the cardiac muscle has to contract. It will be seen from the figure that the force of the ventricular contraction increases with the diastolic volume until the heart becomes overdistended and a rise in diastolic pressure occurs. The force of the contraction then falls off (compare with fig. 98a), the two curves approaching one another and finally meeting.

Starling has expressed this fundamental principle of cardiac behavior in what has been termed the *Law of the Heart*, namely, that "the energy set free at each contraction of the heart is a simple function of the length of the fibers composing its muscular walls." Thus the heart fibers automatically gain the necessary energy to eject the greater load of blood which fills its cavities during diastole or to discharge its contents against a raised arterial pressure. In the latter instance the ven-

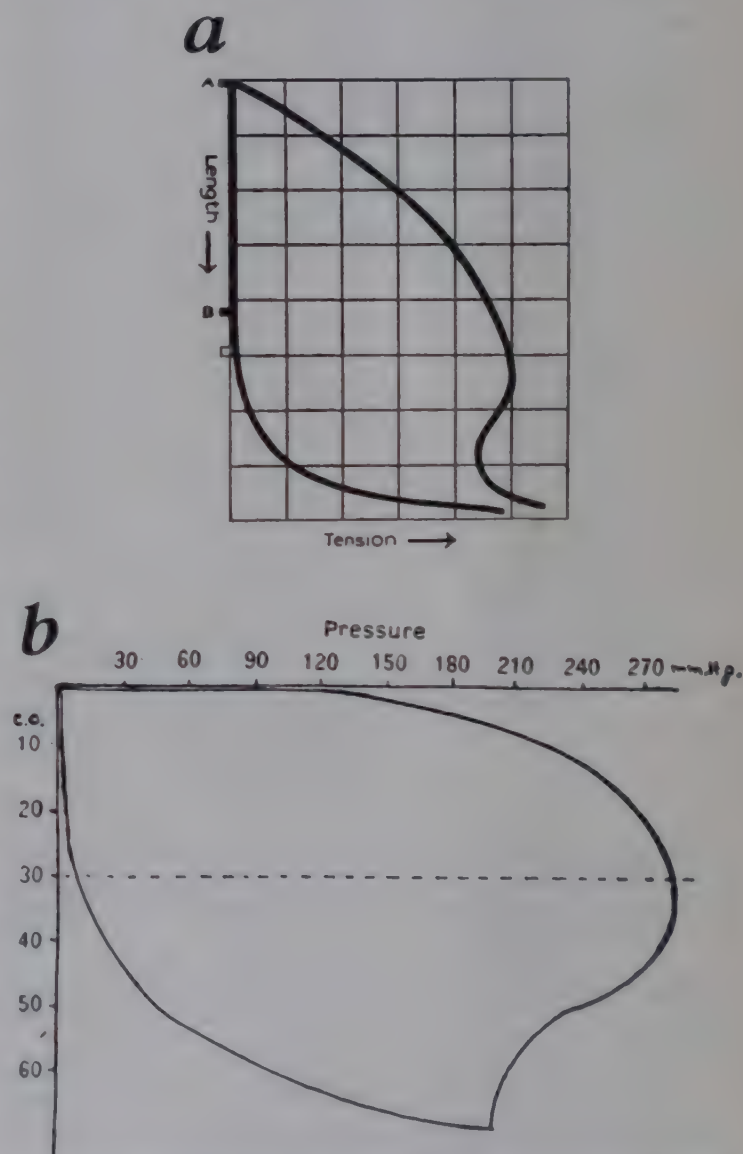

FIG. 98. Showing (a) the relation of initial length to the tension developed by skeletal muscle contracting isometrically, and (b) the relation of diastolic ventricular volume (initial length) to systolic pressure (see text). (After Starling and associates.)

tricle for the first beat or two after the pressure has been raised does not expel the full quantity of blood, but retains a part; this serves to increase the diastolic volume beyond that existing before the pressure was raised, and so to increase the force of the subsequent contraction. The greater energy liberation associated with the increased diastolic volume is attributed to the greater extent of chemically active surface which naturally results from elongation of the fibers.

The results of the experiments of Anrep and Segall are also confirmatory of Starling's conclusions. These observers found that when the isolated frog's ventricle contracted isometrically the contractile force, up to a point (systolic pressure), increased proportionately with the filling of the ventricle (diastolic volume); the maximal tension developed when the ventricle was filled to $\frac{2}{3}$ of its maximal capacity. Filling beyond this caused a rise in the initial (diastolic) tension accompanied by a reduction in the developed tension (fig. 99). Katz was able to dissociate the effects of these two factors upon the development of tension by the turtle heart. When initial tension was varied but initial length kept constant, or the converse, or when both were varied in the same or in opposite directions, the results always indicated that initial length was the factor which determined the force of the contraction. Changes in initial tension amounting to over 200 mm. H₂O were usually without effect upon the height of the intraventricular

FIG. 99. Showing the effect of graded increases in filling of the frog's ventricle upon the tension developed in isometric response; --- initial tension. (Redrawn from Anrep and Segall.)

pressure provided the diastolic volume was kept constant.

It has also been shown by Starling and Visscher that the oxygen consumption of the heart muscle, i.e., the total energy expenditure, is directly proportional to fiber length (diastolic volume). The ratio $\frac{\text{O}_2 \text{ consumption}}{\text{diastolic volume}}$ remained constant though diastolic volume varied widely. The work performed by a heart in first-class physiological condition also bears a linear relationship to diastolic volume and consequently to the oxygen consumption. On the other hand, when as a result of fatigue the condition of the heart deteriorated, its diastolic volume was much greater in proportion to the work performed than was the case with the well-conditioned heart, i.e., the ill-nourished muscle fiber in order to gain energy for the performance of a given amount of work must

be stretched to a greater extent. Nevertheless, whether the condition of the heart muscle was good or bad the relationship between oxygen consumption and diastolic volume was the same (fig. 100). This means, clearly, that for the performance of a given piece of work the poorly nourished heart uses more oxygen (since it dilates more) than does a heart in good condition; or put

FIG. 100. Lower chart shows the work done plotted against the oxygen consumed. In calculating the work of the heart the velocity factor (p. 116) was neglected. Upper chart gives data from the same experiment, work being plotted against the diastolic volume of the ventricles. The volumes are expressed as x plus known values. The x represents the lowest value of the volume during the experiment, which is impossible to measure when a cardiometer is used to record heart volume. The cardiometer enables one to measure only an increase over this minimum value. The figure shows a direct correspondence between work done and ventricular volume. (After Starling and Visscher.)

in another way, the proportion of the total energy expenditure which appears as mechanical work (efficiency) is lowered when the heart muscle departs from its prime physiological state.

PATHOLOGICAL PHYSIOLOGY OF CARDIAC LESIONS.
CARDIAC DILATATION AND HYPERTROPHY

The enlargement (dilatation and hypertrophy) of the diseased heart is a compensatory reaction.

In aortic regurgitation, for example, the heart receives blood not only from the auricles but also from the aorta as a result of the incompetence of the aortic valves. The diastolic enlargement of the ventricular cavity which is required for the accommodation of the greater blood mass also enables the heart to develop the energy necessary for the ejection of the extra blood during systole.

FIG. 101. Diagram illustrating the reserve of the normal heart and of the heart in aortic regurgitation (after Lewis). In column A the reserve power of the normal heart, i.e., its capacity for work is represented as being several times greater than that required for rest. In column B the greater proportion of, but not all, the reserve is drawn upon to perform the extra work entailed in strenuous muscular exercise. Column C represents the heart in aortic regurgitation but with an efficient myocardium. It will be noted that the work required of the heart during rest is increased but its reserve is diminished to only a small extent; it is therefore capable of performing the extra work required for vigorous muscular exercise (column D). In columns E and F the reserve of the heart muscle is represented as falling short of the requirements of strenuous exertion. The reserve is reduced still further in column G, and in column H it has gone entirely, the heart muscle being capable only of meeting the requirements of rest. The subject is dyspneic during rest, and congestive heart failure is imminent or has already supervened.

Cardiac dilatation therefore whether under physiological conditions (physiological dilatation) or in association with heart disease (pathological dilatation) is the means whereby the heart mobilizes its reserves of energy (fig. 101). The so-called reserve power of the human heart, i.e., its capacity for work, resides in the extensibility of its muscle fibers, within the physiological limit. It is apparent then that the nearer the fiber during diastole

approaches its maximal physiological length the greater will be the encroachment upon the heart's reserve. A well-developed and efficient heart in order to gain sufficient power to accomplish a certain amount of extra work need dilate relatively little and is capable of discharging easily as much blood as it receives. The venous pressure in consequence shows little tendency to rise and the pulse is not greatly accelerated. On the other hand, the smaller heart or the heart with a myocardium weakened by disease, ill-nourishment or oxygen lack, when given an equivalent amount of work to perform must dilate to a greater extent in order to liberate the required energy. Indeed, an ill-equipped heart may, as a result of some extra burden, be dilated to its physiological limit and still be unable to increase its output per beat. The heart accelerates its beat as this point is approached (Bainbridge reflex) in order to increase its output. When the full physiological length of the fiber has been attained and the optimal pulse frequency developed, the heart has reached the limits of its powers. Blood then accumulates in the cardiac chambers, the venous pressure rises, the circulation through the capillaries is slowed and the blood gives up a greater proportion of its oxygen load to the tissues (stagnant type of anoxia, pp. 147, 221 and 359).

THE PERMANENT EFFECTS OF EXERCISE UPON THE HEART

The belief has been widely held that strenuous muscular effort is conducive to cardiac dilatation and hypertrophy. A proportion of athletes have, of course, suffered from heart disease and an occasional racehorse has died with a dilated and hypertrophied heart. Instances of this sort have been cited in support of such a view. It is now agreed, however, that the cardiac enlargements under these circumstances are the result of preexisting disease and that the healthy heart cannot be dilated beyond its physiological limit, nor will a bout of strenuous exercise "strain" the healthy heart muscle or cause it to fail. In a healthy person the functional capacity of the heart and of the skeletal musculature are apparently so proportioned to one another that the greatest venous inflow which the muscles can provide is taken care of by the reserves of cardiac energy. The healthy heart of the marathon runner or oarsman does not hypertrophy to a pathological degree. It has also been shown by X-ray examination that the diastolic diameters of the healthy heart are not materially increased during strenuous exercise and that the

systolic size is actually less than it is during rest; that is, the heart empties more completely. It may, therefore, be concluded that acute dilatation or chronic dilatation with hypertrophy is the result of some diseased state of the heart itself.

It should not be concluded, however, that muscular training exerts no effect upon the size of the heart. Mitchell, for example, found that the heart-size of a group of undergraduates at Cambridge underwent a gradual increase over a period of a few years of athletic training. This was accompanied by a reduction in pulse rate (see p. 224). Lindhard observed an increase of 20 per cent in the resting cardiac output as a result of physical training. Others have reported more marked effects in persons indulging in very arduous types of athletics. Eyster, on the other hand, could demonstrate no increase in the average heart size of a group of young athletes when compared with that of a group following a more sedentary life. The evidence taken in review indicates that athletic pursuits, especially of a strenuous nature, may cause a moderate but definite increase in cardiac bulk. This, however, is purely physiological and is proportioned to, or only slightly in excess of, a development of the skeletal muscles. That is, to say, the normal ratio of heart weight to body weight shows no change or a very moderate one.

THE NATURE AND CAUSE OF THE HYPERTROPHY IN CARDIAC DISEASE

The average weight of the normal adult heart is 300 grams (250 to 350); it constitutes from 0.40 to 0.50 per cent of the body weight. In disease 500 grams is not an unusual weight and hearts weighing 1000 grams or more are occasionally seen. The commonest causes of cardiac hypertrophy are valvular disease and hypertension. In the latter, the left ventricle is primarily involved but in valvular disease one or other ventricle, or both ventricles may be enlarged; in some instances the auricles are also dilated and their walls hypertrophied. Other less common causes of cardiac enlargement are coronary disease, arterio-venous aneurysm, hyperthyroidism, adherent pericardium, anemia and congenital cardiac defects. When the enlargement is due predominantly to hypertrophy it is sometimes referred to as *concentric*, when marked dilatation exists as well, the enlargement is said to be *eccentric*. The increased bulk of the ventricular muscle is due, not to a multiplication of its fibers, but to an increase in the size of each fiber. The sarcoplasm is more abun-

dant and the fibrillae more numerous. There is also frequently an increase in the connective tissue between the fibers.

The hypertrophy is probably always preceded by some degree of dilatation. The permanent lengthening of the fibers consequent upon the latter, as already mentioned, tends to reduce the cardiac reserve since they are thereby brought nearer to the point of maximal extension. The hypertrophy, on the other hand, has the effect of increasing the power of the fiber at this new length with the result that the heart's reserve power is raised and may be restored nearly to its normal value (fig. 101). Such a heart is said to be compensated. In experimental lesions the hypertrophied heart is reported to have a reserve power quite as great as that of the normal heart.

The *cause of the cardiac hypertrophy* is not easily explained. Increased work (induced by valvular defect, hypertension, etc.) is not the only, or even perhaps the major, factor in its production. In the first place, the extra burden thrown upon the heart by a valvular lesion is often not sufficient to encroach to any great extent upon the reserve power of the heart and the grade of hypertrophy is very often out of proportion to the amount of extra work which the heart is called upon to perform. Arterial hypertension if it develops gradually may, for example, cause little hypertrophy though the work of the heart is increased by 40 per cent. Also, in a large proportion of cases of mitral stenosis the hypertrophy of the left ventricle is as great as that of the right where the burden falls, and in aortic disease the right as well as the left ventricle may be increased in bulk (Lewis). Finally, cardiac hypertrophy occurs, as in coronary disease, when there is no evidence of increased work.

The experiments of Eyster and his associates throw some light upon this question. They produced aortic regurgitation in dogs by passing an instrument down the right carotid artery to the heart and cutting the aortic valves. The ventricle, being suddenly subjected during its relaxation phase to the high aortic pressure, became acutely dilated. The dilatation (as shown by roentgenograms) disappeared within a few days but hypertrophy gradually developed from then on. An effect comparable to aortic stenosis was also induced by constricting the ascending aorta with a rubber band. Similar changes in heart size resulted. In other animals the band was removed after from 3 to 6 days, at which time the ventricular dilatation had reached its maximum.

Though the heart was relieved of the extra work, hypertrophy was not prevented. This came on gradually, as in those instances in which the stenosis was not relieved, and was complete by about the eightieth day. A second constriction again caused immediate dilatation followed by progressive hypertrophy. Similar results were obtained by massive transfusions which caused distension of the right ventricle. Histological examination of the heart during the stage of dilatation revealed thinning and hydropic degeneration of the heart muscle, which were ascribed to the injurious effect of the acute stretching of the muscle fibers. In the later stages the degenerative changes had disappeared and a pure hypertrophy alone was evident. The hypertrophy was therefore considered to be a reaction to injury brought about by the sudden dilatation.

These observations are of the utmost importance in gaining an insight into the probable sequence of events in the hypertrophy of the human heart. Overstretching of the fibers is apparently associated in some way with their overgrowth. The increased fiber length may be brought about by an excessive load resulting from some mechanical defect such as aortic regurgitation. Injury to the muscle is thereby induced. Or, on the other hand, the overstretching may be the result of a primary weakening of the myocardium, as in coronary disease or infective or toxic processes, the fiber being forced to lengthen unduly in order to liberate the required energy. The manner in which increase in fiber length brings about the overgrowth is unknown, but the experiments of Starling and Visscher suggest elevation of the metabolism of the muscle as a possible explanation (p. 218). It has been mentioned that, for the performance of a given amount of work, the ill-conditioned myocardium as compared with a healthy one has a much greater oxygen consumption. This view accords with the facts that a diseased myocardium may hypertrophy even though its work is not at all increased, and that a great increase in the burden of the healthy muscle can be borne with only a very moderate degree of overgrowth.

HEART FAILURE ("CARDIAC DE-COMPENSATION")

When the heart is unable to maintain an efficient circulation during rest or mild exertion the condition is spoken of as heart failure. In most instances signs of venous congestion—increased venous pressure, capillary engorgement, edema,

etc.—appear, the term *congestive heart failure* being then applied.

The heart with a valvular defect or one which is forced to work against some abnormal resistance may, if it possesses healthy muscle, continue to perform its functions efficiently for years. The state of the heart muscle rather than the valvular lesion itself has come to be recognized as the important factor determining the onset of cardiac failure. The healthy myocardium possesses such great reserves of energy that there is little likelihood of its ever being faced with a resistance which it cannot effectively overcome—not until the myocardium itself becomes diseased do the signs of circulatory failure make their appearance.

Increased resistance to the output of the right ventricle results from such pulmonary conditions as emphysema or fibrosis of the lung; from pulmonary or mitral stenosis; or from failure of the left ventricle. Aortic stenosis, hypertension, or congenital narrowing (coarctation) of the aorta increases the resistance to the output of the left ventricle.

CAUSES OF CARDIAC FAILURE

Circulatory failure may be precipitated by the reduction in the myocardial reserve of a heart which has been working against some inordinate resistance or at a mechanical disadvantage; or it may be the result of an increase in the burden of a heart whose reserve has already been lowered by myocardial disease. Among the commoner causes are:—

(a) Infections, especially of the respiratory tract. The increased cardiac work resulting from the rise in metabolic rate caused by the fever, direct poisoning of the myocardium, and cough all conspire to reduce the cardiac reserve to the point where the failure ensues.

(b) Excessive muscular effort.

(c) Chronic pulmonary conditions, emphysema, bronchitis, etc., accompanied by much coughing which exerts its effect mainly through the muscular effort involved.

(d) Pregnancy.

(e) Rapid heart action, e.g., auricular fibrillation, paroxysmal tachycardia, etc. It should be remembered that the heart works very uneconomically at high rates of beating, i.e. the heart expends more energy for the performance of a given amount of work at high than at low rates of beating. One reason for this is that the cardiac cycle is shortened mainly at the expense of the diastolic (rest) period and the period of ejection (time during which work is actually performed). The period of isometric contraction (during which energy is ex-

pended in raising the intraventricular pressures above the arterial pressures but no work is done) is shortened comparatively little. This latter period is, therefore, in a sense a waste period, and its total time per minute is greater the more rapid the heart rate.

(f) Hyperthyroidism.

On the other hand, the heart muscle may be so weakened by disease—coronary sclerosis, acute infective processes, severe anemia, anoxia—that cardiac failure ensues though no valvular defect or other condition exists to increase the work of the heart.

The validity of the application to clinical cases of Starling's law of the heart, which was based upon acute animal experiments, has been tested by Starr and his associates. The work of the heart, as determined in 140 normal persons and in a number of patients who had recovered from congestive heart failure, was plotted against the heart volume. The work of the heart was calculated from the cardiac output and the blood pressure; the heart size was determined roentgenologically. In the cardiac patients, the work performed for a given heart volume was much less than in normal subjects. These authors concluded that Starling's law holds true for the human heart in congestive failure.

There is some difference of opinion concerning the fundamental cause of cardiac heart failure. According to one view (Katz and his associates) the total energy liberation of the heart muscle (see p. 192) at a given fiber length is reduced to the point where an adequate circulation cannot be maintained. Visscher, on the other hand, considers that, in the majority of cases at any rate, the heart fails because of a decrease in its mechanical efficiency (that is, because of a reduction in the proportion of the total energy output which is expended in doing useful work). Starling and Visscher found that this was invariably the cause of cardiac failure in the heart-lung preparation of the dog. In one of their experiments of 4-hours duration, the oxygen consumption rose from 360 cc. to 590 cc. per hour, the diastolic volume increased by 42 cc. and the efficiency fell from 9.5 per cent to 5.8 per cent.

THE SIGNS AND SYMPTOMS OF CONGESTIVE HEART FAILURE

The chief manifestations are: increased venous pressure; dyspnea; cyanosis; congestion and consequent enlargement of the liver and spleen, pulsation of the liver is not uncommon, and there

may be jaundice; oliguria and albuminuria; and edema.

The manner in which the chief signs and symptoms of cardiac failure are produced has been a question of some controversy. According to one view—the *forward-failure theory*—they are the result of a reduced cardiac output and consequent diminished flow of blood through the tissues. The dyspnea, for example, has been attributed to slowing of the circulation through the medulla (respiratory center); the cyanosis to the diminished flow through the vessels of the skin and the greater coefficient of oxygen utilization; the edema to increased capillary permeability induced by the local asphyxia. In cardiac failure resulting from paroxysmal tachycardia, heart block, or acute myocardial disease, there may be a marked reduction in the cardiac output and in these instances the manifestations may be explained upon the forward-failure theory. In the majority of cases of heart failure, however, the clinical picture is interpreted best upon the basis of the *backward-failure theory* ("back-pressure" theory), which may now be briefly stated. As the myocardium fails, blood accumulates in the ventricle which in consequence dilates. The muscle fibers become stretched to a point where they offer a greater resistance to the incoming venous blood, a rise in auricular pressure follows which is transmitted backwards. The heart does not fail as a whole; failure of the left ventricle may precede failure of the right by a considerable interval or death may occur from failure of the left or the right ventricle alone.

When the left ventricle fails first and does not adequately discharge its contents the pressure of blood in the left auricle and pulmonary veins rises. The high pressure in the pulmonary circuit causes engorgement of the vessels of the lung. The total volume of blood in the lungs is greatly increased and the velocity of flow in the individual vessels diminished. The distended vessels encroach upon the air spaces, the vital capacity is reduced, the lung tissue is rendered less expansile, dyspnea and cough result (p. 355). Increased resistance in the pulmonary circuit, such as results from stenosis of the mitral orifice, even in the absence of left ventricular failure tends also to cause pulmonary engorgement accompanied by dyspnea and cough, especially upon exertion. Pulsus alternans (p. 202), gallop rhythm (p. 179) and cardiac asthma are characteristic features of left ventricular failure.

So long as the right ventricle continues to con-

tract forcibly and discharge its contents against the increased resistance in the pulmonary circuit, the systemic vessels are not congested. Subsequent failure and dilatation of the right ventricle are attended by a rise of right auricular pressure and of the pressure in the systemic veins, with congestion of the liver and abdominal viscera. Signs and symptoms (edema, cyanosis, etc.) appear, due to engorgement of the peripheral vessels and slowing of the blood flow through them. But, though the velocity of the blood in the peripheral capillaries is reduced, owing to their distension and the consequent general enlargement of the capillary bed the total volume of blood flowing through the periphery may show little change (see p. 148).

The following observations militate against the forward-failure hypothesis as an explanation of the manifestations of the usual type of cardiac failure, and argue for the "back-pressure" conception.

(1) Reduction in the circulation rate, though commonly, is not invariably associated with congestive heart failure; the reduction in cardiac output, when a reduction does occur, does not run parallel with the severity of the symptoms. Moreover, the improvement of the clinical condition which follows the administration of digitalis is not always attended by an increased circulation rate.

(2) The fact that one ventricle can fail independently of the other and that left-sided failure is associated with pulmonary congestion and right-sided failure with systemic congestion can be explained upon the basis of "back-pressure," but not by the forward-failure hypothesis (reduced cardiac output). The reduction in vital capacity in failure of the left ventricle or in obstruction (stenosis) at the mitral orifice is accounted for most satisfactorily by a rise of pressure in the pulmonary circuit and congestion of the lungs. Congestion of the lungs and diminished expansibility, as a result of compression of the pulmonary veins, have been demonstrated in animals.

(3) Venesection, a valuable therapeutic measure in congestive heart failure causes a reduction of the cardiac output.

(4) Reduction of the cardiac output in animals does not reproduce the ordinary picture of heart failure.

(5) Edema cannot be satisfactorily explained by the forward-failure hypothesis. The edema fluid is of very low protein content which is in accord with the view that it is formed as a result of increased filtration pressure.

If it were the result mainly of capillary damage the protein content would be nearer that of plasma.

The backward-failure theory does not necessarily imply that the auriculo-ventricular valves become incompetent (tricuspid in the case of right-sided failure and mitral in the case of left-sided failure) with consequent regurgitation of blood into the right or left auricle. Auricular pressures can be raised without the occurrence of any actual backward leakage of blood.

The inefficiency of the heart in congestive failure. For the performance of a given amount of work the oxygen usage of the subject of congestive heart failure is considerably higher than that of a healthy person. From experiments upon animals (p. 218) one would suspect that the heart is responsible to some extent at least for the higher oxygen consumption. Resnik and Friedeman found that the basal metabolism of patients with heart failure was from 10 to 60 per cent above normal, and that improvement in the cardiac condition was accompanied by a reduction in the amount of oxygen consumed. They conclude that increased respiratory effort (i.e., the increased work of the respiratory muscles) accounts for the greater part, but that a considerable share of the extra oxygen is used by the heart itself. Other factors which have been suggested as being responsible, e.g., thyroid stimulation as a result of circulatory alterations in the gland, apprehension and discomfort, or expansion of the capillary bed caused by the high venous pressure, played no rôle in the opinion of these authors in producing the high metabolic rate.

Exercise tolerance tests. A useful test of cardiac function in heart disease based upon the metabolic response to exercise has been devised by Katz and his associates. The greater proportion of the increased oxygen consumption occurs after the exercise. These observers, therefore, determine the oxygen consumption before, during and for 15 minutes after the performance of a measured amount of work. The total oxygen consumption throughout the test is compared with that for the same period at the pre-exercise rate. The difference between the two estimations gives the excess metabolism (p. 620) of the exercise which is expressed in cubic centimeters of oxygen consumed per kilogram-meter of work per square meter of body surface. A simple but valuable aid in estimating cardiac reserve is the determination of respiratory and cardiac acceleration after a standard light exercise, e.g., 50 hops 3 inches from the floor at one second intervals.

CHAPTER XXVI

THE OUTPUT OF THE HEART

DEFINITIONS AND GENERAL CONSIDERATIONS

The output of the heart per beat is spoken of as the *systolic discharge* or the *stroke volume*, and the output per minute as the *minute volume* or the *circulation rate*. The value of the latter is simply the product of the stroke volume and the pulse rate (pulse rate \times stroke volume = minute volume) and the minute volume divided by the pulse rate gives the stroke volume. The quantity of blood ejected by each beat of the left ventricle in the average healthy man during rest is from 60 to 70 cc. An equal quantity is, of course, discharged at the same time by the right ventricle, making a total for the whole heart of from 120 to 140 cc. The contents of the left ventricle are ejected against a much higher mean arterial pressure than the contents of the right; the mean pressure in the pulmonary artery being about $\frac{1}{3}$ of that in the aorta. The minute volume is usually expressed in terms of one ventricle. The output of one ventricle obviously represents the quantity of blood flowing through the lungs, or through the systemic vessels, during the same period. It is for this reason the value expressing the minute volume of the ventricle is referred to as the circulation rate.

It is evident that the heart can increase its output per minute by increasing its stroke volume and maintaining its rate constant or, conversely, by increasing its rate and maintaining a constant stroke volume. Again, both these factors may be called into play. When the heart rate accelerates the output per beat can be kept constant only if the venous inflow is adequate and so, only under such circumstances can the minute volume be increased. If, for example, the beats of the heart have occurred at the end of a period of rapid filling, i.e., before or at the moment that the heart chambers are filled, simply increasing the heart rate will cause the beats to fall earlier in the period of rapid filling. Reduction in the stroke volume in proportion to the increase in rate must result and no increase in the minute volume can, therefore, occur (see table 18, p. 216). At very rapid heart rates, as in paroxysmal tachycardia, a point is reached at which the heart does not relax sufficiently between beats to take on an adequate load of blood and the minute volume becomes reduced.

If, on the other hand, the beats have been occurring some time after the period of rapid filling, i.e., a period of diastasis exists, then an increase in heart rate will, by shortening or abolishing this period, or by preventing its appearance when the inflow is augmented, increase the output. Consequently, when the venous return is increased as in muscular exercise, the greater mass of blood is readily accommodated by the large well-developed heart and there may be no period of diastasis, no rise in venous pressure; the heart rate then shows less tendency to increase. The hearts of some athletes show no increase in rate, whatever, during exercise; the resting stroke volume of such hearts may be double or more that of an ordinary person, namely 120 to 130 cc. In the smaller heart the greater inflow causes the heart to fill earlier in diastole, the venous pressure rises and as a result of the Bainbridge reflex the heart accelerates. Little change in stroke volume may occur, the greater minute volume being brought about almost entirely by an increase in the frequency of the beats. In the majority of healthy persons both factors—increase in heart rate and increase in stroke volume—play a part in the production of a greater cardiac output. Individuals differ, however, in the extent to which each factor contributes. In the athlete, as just mentioned, the output is increased chiefly through an increase in the stroke volume; increase in heart rate plays a very minor rôle, whereas in the sedentary individual the latter factor exerts an important effect.

The contribution which cardiac acceleration can make toward the minute volume is strictly limited, for from 180 to 200 is about the maximum rate to which the healthy heart can be speeded up. This is only about $2\frac{1}{2}$ to 3 times the normal rate. With a constant stroke volume, therefore, cardiac acceleration could not increase the minute volume more than two and a half to three times. In muscular exercise, the oxygen consumption is increased many fold. There are only two possible means whereby the tissues can be supplied with the extra oxygen, namely, by an increased circulation rate or a greater coefficient of oxygen utilization (i.e., the removal of more oxygen from each unit of blood, p. 322). Were the cardiac output

solely dependent upon a rise in pulse rate, then the circulatory factor could, obviously, increase the supply of oxygen to the tissues three times, at the most, over that of the resting state. If no change in the stroke volume occurred, then, in order to increase the oxygen supply, say 10 times, the coefficient of oxygen utilization would require to be increased between three and fourfold. As a matter of fact, the cardiac output in a robust subject may increase 9 times during strenuous exercise, and the oxygen consumption 12 times. In such an instance it must be concluded (1) that the stroke volume increases over 3 times (even at a maximum pulse rate), and (2) that the oxygen requirement is satisfied largely by a rise in the circulation rate, an increase in the coefficient of oxygen utilization playing a less prominent rôle.

The proportion in which each of the two factors just mentioned—increased circulation rate and increased coefficient of oxygen utilization—contribute in bringing about the greater oxygen supply to the tissues varies, however, in different persons and with the type of exercise. In very light exercise involving slow movements the coefficient of oxygen utilization is increased to a proportionately greater extent than is the cardiac output. With moderately severe exercise, on the other hand, the coefficient of oxygen utilization is usually about doubled while the cardiac output is increased fourfold or so. This would permit an eightfold increase in oxygen consumption. As the exercise becomes more severe the circulation rate increases to a less extent proportionately than the coefficient of oxygen utilization, and in exhausting effort a point is reached where the cardiac output shows no further increase, the coefficient of oxygen utilization from then on rising with the oxygen consumption. The rise in the coefficient of oxygen usage in muscular exercise is attributed to the diversion of a larger proportion of the total blood volume through the contracting muscles. The production of acid metabolites (carbon dioxide and lactic acid) and the rise in temperature also lower the affinity of the hemoglobin for oxygen which, in consequence, is given up more readily (p. 321) to the tissues.

The extent to which these two factors operate to satisfy the oxygen requirement also varies with the particular muscle groups which are exercised. Muscles, such as those employed in walking or running, whose action is more efficient in increasing the venous return tend to increase the cardiac output more than those which have

not this effect, even though the total oxygen consumption in both instances is the same. Swimming is an exercise which causes a relatively great increase in the cardiac output. Several factors other than the exercise itself, namely, increased heat loss, respiratory stimulation and the pressure of the water are largely responsible for the greater cardiac response in this type of exercise. There is some evidence that, as a result of training, the coefficient of oxygen utilization tends to increase during exercise, thus sparing the work of the heart.

THE OUTPUT OF THE HEALTHY HEART. NORMAL STANDARDS. PHYSIOLOGICAL VARIATIONS

The minute volume of the heart under basal conditions¹ varies, in different individuals, from 3 to 4.6 liters. The value for a given person was found by Grollman to be remarkably constant, determinations made from time to time varying by no more than 2.5 per cent. Grollman has also shown that the basal cardiac output is a function of the surface area of the body. For normal persons the minute volume per square meter of body surface—the *cardiac index* as it is termed—has an average value of 2.2 liters. In a group of 50 normal adults the index had an average deviation from the mean of 6.4 per cent. The cardiac output then is proportional to the basal metabolism (p. 533) and like the latter can be predicted for a normal person, with a small error, from the surface area. The average basal cardiac output per kilogram of body weight is 62 cc. As already mentioned the average volume of blood ejected per beat (stroke volume) is from 60 to 70 cc.

The following physiological conditions vary the cardiac output.

Muscular exercise. In strenuous exercise the output increases from the basal level of between 3 and 4.6 liters per minute to from 19 to 37 liters, according to the individual; the stroke volume increases from a resting value of from 60 to 70 cc. to from 100 to 200 cc.¹ The effect of muscular exercise upon the circulation rate is considered in more detail above.

Temperature. No change in cardiac output occurs until the environmental temperature exceeds 30°C. Temperatures above this cause a very moderate increase (5 to 30 per cent) in minute volume.

Digestion of food causes an increase above the

¹I.e., with the body recumbent and at rest, at room temperature 20°C and 12 hours after having partaken of food or drink (p. 533).

basal level of from 30 to 40 per cent. This level is reached about 1 hour after the meal, persists for about 3 hours and then gradually declines. The extra strain placed upon the diseased heart following a meal probably accounts for the attacks of angina pectoris (p. 280) which sometimes occur at this time. Ingestion of fluids also increases the cardiac output to a moderate degree. Both the cutaneous and splanchnic regions share in the increased blood flow.

Variations in oxygen and carbon dioxide tensions in the inspired air (pp. 213 and 214).

Sleep causes no reduction in the minute volume below the basal level.

Posture. Schneider and Crampton find that the minute volume is somewhat greater in the recumbent than in the erect position with the subject standing quietly. After prolonged standing, in most healthy persons the output of the heart remains unchanged or decreases slightly. In certain subjects, who upon prolonged standing show poor circulatory compensation for the effect of gravity (p. 139), the pulse pressure decreases by 20 mm. Hg or so and the cardiac output is reduced markedly; fainting may occur.

Emotional excitement, anger, fear, etc., cause a slight increase which varies in magnitude (from 10 to 25 per cent) in different subjects.

Pregnancy increases the minute volume, but only in the later months; the increase amounts to from 45 to 85 per cent.

PATHOLOGICAL VARIATIONS IN THE CARDIAC OUTPUT

A. Conditions which increase the cardiac output

(1) *Hyperthyroidism.* It has been mentioned that the basal cardiac output is proportional to the basal metabolic rate. It therefore follows that the former will be increased in hyperthyroidism; as a matter of fact the output in this condition is raised from 50 to 100 per cent. The shunting of blood from the arterial to the venous side through the dilated thyroid vessels may possibly be a contributory factor (p. 675) in the production of the increased output. After operation the output falls with the decline in the metabolic rate. Within the last few years thyroidectomy has been employed in angina pectoris and congestive heart failure with the object of lowering the metabolic rate and so of reducing the work of the heart. This mode of treatment is resorted to even though no evidence of hyperthyroidism exists. The thyroid is removed completely; thyroid extract

is then administered with the aim of maintaining the basal metabolic rate at a level a little above that at which signs of hypothyroidism appear (−25 to −30). The operation is of benefit in angina pectoris, but its justifiability in other cardiac conditions is seriously questioned.

(2) *Anemia* (see p. 256) increases the output.

(3) *Anoxemia* increases the cardiac output unless severe or prolonged; then the output declines owing to the injurious effect upon the myocardium.

(4) *Fever.* The increase is due mainly to the elevated metabolism (p. 632).

(5) *Angina pectoris.* During the attacks of pain, the cardiac output is definitely increased over that in the periods between attacks.

(6) *Arterio-venous fistula* (arterio-venous aneurysm). A communication between a large vein e.g., the femoral, and its companion artery results in a fraction ($\frac{1}{3}$ – $\frac{1}{2}$) of the blood ejected from the left ventricle being short-circuited, or shunted, to the right side. The velocity of the blood on the proximal side of the fistula is increased, that on the distal side reduced. Trauma is the most common cause of the condition. A pulsating swelling is frequently present at the site of the anastomosis, the heart rate is elevated, the heart becomes enlarged and, according to Harrison and associates who studied the condition experimentally, the minute volume is increased. An increase of 100 per cent in the cardiac output was found in dogs in which a femoral arterio-venous anastomosis had been produced. Compression of the artery or closure of the stoma causes an immediate reduction in the heart rate. Grollman from studies of the condition in man also concluded that the cardiac output was increased.²

The acceleration of the pulse is ascribed by Lewis and Drury to the reduction in the mean arterial pressure (Marey's law, p. 209) resulting from the leak through the arterio-venous fistula, and not to an increase in venous pressure (Bainbridge reflex). They found that after the administration of atropine, which increased the heart rate to 130 beats per minute, compression of the artery caused a reduction in rate of only two beats per minute. This indicates that the reduced rate, which occurs when the artery is compressed without previous treatment with atropine, is due to a vagal reflex. The enlargement of the heart is

²Ellis and Weiss (Am. Heart J. 1930, 5, 3) observed in patients only a slight tendency towards reduction in the cardiac output when the aneurysm was compressed or after operative cure.

considered to be due to deficient nourishment of the myocardium caused by the lowered aortic pressure and the consequent reduction in coronary blood-flow (p. 220). The effects upon the arterial system of an arterio-venous anastomosis resemble those of aortic regurgitation—low diastolic pressure, high pulse pressure (100 mm.) and collapsing pulse—though the blood in the one case leaks into the ventricle during diastole, in the other into the venous system. Capillary pulsation occurs in both conditions.

B. Conditions which reduce the cardiac output

(1) *Cardiac irregularities.* (a) *Paroxysmal tachycardia.* Barcroft and his associates found the output reduced to half the normal value in a subject of this condition. Before the onset of the attack the pulse rate was 64 per minute, the stroke volume 77.5 and the minute volume about 5 liters. During the attack the pulse rate was 198 and the stroke volume 12.9 cc.; the output per minute was therefore 2.5 liters. (b) In *auricular fibrillation* the output is frequently reduced since this irregularity so often accompanies myocardial failure (see below). (c) In *complete heart block* with an efficient myocardium the output under ordinary circumstances shows little alteration from the normal. Since the pulse rate is from 35 to 40 per minute the stroke volume is elevated well above the normal average (100 cc. or more). In other instances associated with coronary sclerosis and myocardial degeneration, the output is definitely reduced. In other subjects again, though the output during rest is normal, the inability of the heart to accelerate fully prevents an adequate output during muscular exertion.

(2) *Valvular disease and myocardial failure.* In the absence of cardiac failure, a valvular lesion, as a rule, causes little change in the output under basal conditions; a reduction is, however, more likely to be found in mitral stenosis than in other forms of valvular disease. Cases which show no reduction in output under basal conditions may, nevertheless, show a much smaller increase in minute volume in response to exercise than does the normal person, the tissues consequently suffer from oxygen lack and cyanosis may appear. The output also remains above the resting level for some time after the exercise has ceased, whereas normally it falls quickly to its previous value. In other subjects of valvular disease but with an efficient myocardium the cardiac output during exercise is not below normal: but, after the termination of the effort, it, usually, as in the

previous group, returns more slowly than is normal to the resting level. When definite weakening of the myocardium supervenes and other signs of heart failure are present, the basal cardiac output is frequently markedly reduced; in other instances, however little or no reduction in output occurs (see p. 223).

Overweight persons with cardiac failure should be benefited by a reduction in their weight. It has been found by Master and his associates, in a series of persons not suffering from heart disease that a reduction of 16 per cent in oxygen consumption, a 30 per cent, decrease in the cardiac output and an average reduction of 35 per cent in the work of the heart may follow loss of weight.

(3) *Myxedema.* The reduction in the cardiac output is roughly proportional to the depression of the basal metabolic rate.

(4) *Adherent pericardium and pericarditis with effusion.* The reduced minute volume is the result of the mechanical interference with the action of the heart. Adherent pericardium interferes with the normal contraction of the heart. Fluid within the pericardial sac prevents full dilatation of the heart during diastole and thus reduces the volume of blood which it can accommodate.

(5) *Pneumothorax* and other pulmonary conditions in which the intrathoracic negative (suction) pressure is reduced (p. 138).

(6) *Surgical shock.* Reduction in the cardiac output occurs early (p. 258).

(7) *Arterial hypertension.* In some cases the minute volume is reduced, in others, probably the majority, it is within the normal range.

(8) *Postoperative.* A pronounced reduction in the cardiac output occurs for a period of from 1 to 4 days following surgical operation (Snyder).

THE EFFECTS OF CERTAIN DRUGS UPON THE MINUTE VOLUME

Adrenaline and *histamine* increase the oxygen consumption and the cardiac output; the effect upon the minute volume is, however, proportionately greater than that upon the oxygen consumption. *Acetylcholine* whose effects in general are very evanescent causes a slight increase in the minute volume. A decided rise in the cardiac output is produced by *nitrites* which, like *acetylcholine*, cause arteriolar dilatation. The increase in the cardiac output caused by *nitrites* is probably a compensatory effect of the lowered peripheral resistance, whereby the blood pressure is maintained near the normal level. *Digitalis* produces no immediate effect upon the minute volume in normal persons, but a slight increase occurs about 6 hours after administration

of the drug, followed by a reduction which persists for twenty-four hours. In subjects of congestive heart failure with auricular fibrillation the output is as a rule though not invariably increased as the cardiac condition improves. *Strophanthin* acts similarly to digitalis. *Atropine* which increases the heart rate to 150 or 180 beats per minute does not increase, as a rule, the cardiac output. *Alcohol* in moderate dosage (35 cc.) causes no more than a slight rise in the cardiac output. Grollman believes the effect to be largely psychic in origin rather than due to the direct action of the drug upon the heart. *Caffeine* increases the cardiac output; *pituitrin* and *morphine* reduce it slightly.

MEASUREMENT OF THE OUTPUT OF THE HUMAN HEART

Any method for the estimation of the circulation rate in man must, of course, be indirect. Several methods have been devised for the purpose. The methods fall into two groups, (1) those based solely upon the Fick principle, and (2) those which involve as well, breathing a foreign gas, e.g., nitrous oxide, ethyl iodide or acetylene.

THE FICK PRINCIPLE

The output is calculated from the difference between the oxygen (or CO₂) content of the venous blood and that of the arterial blood, and the total oxygen consumption (or CO₂ elimination). It must be evident that if the quantity of oxygen which a unit of blood delivers to the tissues (or takes up from the lungs) be known, together with the total quantity of oxygen consumed over a given period, then the volume of blood which had been engaged in the carriage of this quantity of gas can be calculated. To take an example. The arterial blood contains about 19 volumes of oxygen per 100 cc. It gives up, let us say, 6 volumes to the tissues, i.e., the mixed venous blood coming to the lungs contains 13 volumes per cent. The total quantity of oxygen consumed per minute is say 250 cc. Then the cardiac output is—

(Total O₂ consumption) (Output per minute)

$$\frac{250}{19 - 13} \times 100 = 4.16 \text{ liters}$$

(Arterio-venous O₂ difference)

The output can be calculated in a similar way from the total carbon dioxide elimination and the arterio-venous carbon dioxide difference (CO₂ in mixed venous blood less CO₂ in arterial blood). The total oxygen consumption (or carbon dioxide elimination) can be readily determined (p. 527).

The arterial oxygen or carbon dioxide content can be obtained by analyzing a sample of blood, or the quantity of either gas in the arterial blood can be calculated from their tensions. The latter, in turn, can be determined from an analysis of the alveolar air. It is difficult, on the other hand, to obtain the oxygen or carbon dioxide content of the *mixed venous blood* and several procedures have been devised for the purpose. It is not permissible simply to take the gas content of the blood in an arm vein since this is not equal to that of the mixed venous blood as it reaches the lungs. In animals the oxygen or carbon dioxide content of arterial blood and of mixed venous blood can be obtained by puncturing, respectively, the left and right sides of the heart. Such a method is usually unjustifiable in the case of the human subject owing to the risks involved, though it is sometimes employed (p. 231).

The method of Douglas and Haldane based upon the CO₂ arterio-venous difference

The CO₂ tension of the arterial blood is obtained from the tension of CO₂ in the alveolar air. The CO₂ tension of the mixed venous blood is obtained by breathing air mixtures containing different percentages of CO₂ from a series of bags, and holding the breath for a sufficient time to allow the mixture in the lung-bag system to come into equilibrium with the venous blood. That gas mixture of which two samples taken a short interval apart have practically the same CO₂ percentage is assumed to be in equilibrium with the venous blood. The whole procedure must not take longer than the time of a single circulation (20 seconds), i.e., the blood which has left the lungs must not be allowed time to return before the second sample is obtained, otherwise the CO₂ tension of the mixed venous blood would be raised artificially as a result of the absorption of CO₂ from the air mixture, and the results be vitiated. That is, the calculated CO₂ content of the mixed venous blood would be too high and the value for the cardiac output, in consequence, too low. Blood passes through the coronary circuit in about 10 seconds so the value for the cardiac output does not include the blood of the coronary system.

Three (or four) bags of 30 liters capacity are first filled with mixtures of air and CO₂. The respective mixtures are made up with proportions of CO₂ which increase in successive bags by 0.5 per cent. Thus, the mixture in bag number one contains approximately 6.5 per cent CO₂; bag two, 7.0 per cent; bag three, 7.5

per cent. The subject makes a maximal expiration into room air and then a maximal breath is taken from bag one. These two respiratory movements are repeated three times in order to ensure thorough mixing in the lungs, and to wash out the alveoli with the gas mixture in the bag. Each expiration is made into room air and each inspiration is taken from the bag. After the final inspiration the breath is held for 2 seconds and then a sharp partial expiration (of about 1600 cc.) is made down the Haldane alveolar-air tube (p. 311) and a specimen taken for CO₂ analysis. Due to the dilution with the lung air (which has a lower CO₂ percentage) this sample will be lower in CO₂ than that of the original bag mixture. The subject continues to hold his breath after this short expiration, and 6 seconds later a full expiration is made in order to expel the remainder of the air from the lungs. A second sample is taken for analysis. If this should show the same CO₂ percentage as the first it would then be inferred that in the interval the venous blood had neither given up nor absorbed any CO₂ from the lungs. In other words, the venous blood and alveolar air would be in equilibrium, and the tension of the CO₂ in the sample the same as that of the venous blood. Usually, however, the second analysis gives a higher value; CO₂ must have been given off by the venous blood, and the CO₂ tension of the latter is, therefore, higher than that of the mixture in bag 1. The same procedure is then repeated with the richer mixture in bag 2 (7.0 per cent CO₂). The second of the two analyses may still be higher than the first. If so, the third bag is employed when the second sample will either be the same or slightly lower than the first sample. The venous CO₂ tension in the latter case would be between that of the second samples of the second and third observations. On the other hand, if after breathing from bag 2 the second sample has a lower CO₂ percentage than has the first, CO₂ must have passed from the lungs to the venous blood (see table 19). With the use of the third bag (7.5 per cent CO₂) the second sample will also be lower, but the difference between it and the first sample will be greater than when the mixture in bag 2 was employed. This method of "straddling" shows that the gas mixture which would be in equilibrium with the venous blood must have a CO₂ percentage somewhere between those of the second samples in the first two observations (between 6.40 and 6.63 per cent in table above). A mixture having this percentage of CO₂ is then employed. When this is inspired and the usual procedure repeated, it is to be expected that there will be practically no difference between the first and second alveolar air analyses.

The CO₂ tension of the mixed venous blood is readily calculated from the CO₂ percentage of the gas sample in equilibrium with it (p. 315). The volumes per cent of CO₂ in the arterial blood and in the mixed venous blood are then obtained from the CO₂ dissociation curve, the lower (oxygenated) curve being employed for this purpose (p. 338).

The total CO₂ elimination per minute is determined

just before the re-breathing procedures by the Douglas bag method (p. 529). Then, if the total CO₂ elimination is, say, 208 cc. per minute and the arterio-venous CO₂ difference is 5 volumes per cent.

$$\frac{208}{5} \times 100 = 4.16 \text{ liters, cardiac output per minute.}$$

METHODS INVOLVING THE USE OF A FOREIGN GAS

Nitrous oxide (N₂O) and *ethyl iodide* (C₂H₅I) have been employed in the past. A method involving the use of *acetylene* (C₂H₂) was introduced in 1929 by Grollman. This gives the most accurate results and has largely superseded the older methods.

If a subject breathes an inert foreign gas (i.e., one which becomes dissolved in the plasma but does not combine with the hemoglobin, lipid or other constituents of the blood) and the quantity which has been absorbed in a given time be known, as well as the coefficient of solubility of the gas in plasma, then the quantity of blood which has

TABLE 19

	CO ₂ PER CENT AIR IN BAG	CO ₂ PER CENT IN ALVEOLAR AIR		PRESSURE OF CO ₂ IN VENOUS BLOOD IN RELATION TO ALVEOLAR AIR
		First sample	Second sample	
(1)	6.50	6.38	6.40	+
(2)	7.00	6.68	6.63	—
(3)	7.50	6.87	6.73	—

passed through the lungs can be calculated. This, in general, is the principle upon which the acetylene or any other foreign gas method is based.

The acetylene method. The subject rebreathes a mixture of acetylene (20 to 25 per cent) and air from a rubber bag (3 liters capacity) until the *lung-bag system* contains a homogeneous mixture. A sample of the mixture is taken and the percentages of acetylene, nitrogen and oxygen determined. The subject continues to rebreathe for 5 seconds. A second sample is then taken for analysis. The entire rebreathing procedure should not exceed the time of a single circulation (20 seconds) in order that no acetylene shall be returned to the lungs, and also that the arterio-venous oxygen difference shall not be altered from that existing prior to the rebreathing period.

The volume of the lung-bag system is reduced during the interval between the taking of the two samples, since the volumes of acetylene and oxygen absorbed are together greater than the carbon dioxide eliminated. Inasmuch as nitrogen takes no part in the respiratory exchanges, an increase in its percentage will be pro-

portional to the reduction of the volume of the mixture in the lung-bag-system. The relative gas volumes in the system at the times of the first and second samples, which may be designated V_I and V_{II} respectively, are therefore calculated from the nitrogen percentages at these times, $V_I:V_{II}::N_{II}:N_I$.

If $(C_2H_2)_I$ and $(C_2H_2)_{II}$ be used to designate the percentages of acetylene in the first and second samples, respectively, then the relative volumes of acetylene in the samples will be $V_I(C_2H_2)_I$ and $V_{II}(C_2H_2)_{II}$; and the volume of acetylene absorbed will be $V_I(C_2H_2)_I - V_{II}(C_2H_2)_{II}$. Knowing the average concentration of acetylene—

$$\frac{(C_2H_2)_I + (C_2H_2)_{II}}{2} = (C_2H_2)_{aver.}$$

in the lung-bag system in the interval between the taking of the two samples, and the coefficient of solubility of the gas, then the quantity absorbed per liter of blood is,

$$\frac{740 (C_2H_2)_{aver.}}{100} \times \frac{B - 48.1}{760}$$

740 = the number of cubic centimeters of acetylene which are dissolved by 1 liter of blood at body temperature when the tension of the gas is 760 mm. Hg
B = barometric pressure
48.1 = tension of water vapor in the lungs

Then:

Quantity of C_2H_2 absorbed during observation
Quantity of C_2H_2 absorbed per liter of blood

$$= \frac{[V_I(C_2H_2)_I - V_{II}(C_2H_2)_{II}] \times [760 \times 100]}{740 (C_2H_2)_{aver.} \times (B - 48.1)}$$

= Blood flow through lungs, i.e., cardiac output during rebreathing

The blood flow through the lungs, thus obtained, is affected by the experimental procedure itself, namely, the rebreathing. In order to obtain the cardiac output for the period immediately preceding the rebreathing period, the arterio-venous oxygen difference and the total oxygen consumption must be determined. Now, the arterio-venous oxygen difference during the actual experiment will be the same as that immediately preceding the period of rebreathing since this is shorter than the time of a single circulation. The oxygen absorption during the rebreathing period is obtained in a manner analogous to that by which the acetylene absorption is obtained. The volume of oxygen absorbed divided by the quantity of blood in liters passing through the lung during rebreathing gives the arterio-venous oxygen difference i.e., the quantity of oxygen absorbed by each liter of blood during its passage through the lungs. Thus—

Arterio-venous oxygen difference

$$\begin{aligned} &= \frac{[V_I(O_2)_I - V_{II}(O_2)_{II}] \times 740(C_2H_2)_{aver.}(B - 48.1)}{[V_I(C_2H_2)_I - V_{II}(C_2H_2)_{II}] \times [760 \times 100]} \\ &= \frac{(O_2)_{diff.} (C_2H_2)_{aver.} \times (B - 48.1) \times (0.00974)}{(C_2H_2)_{diff.}} \end{aligned}$$

The factor 0.00974 is derived by combining the constants 760 and 100, and 740,—

$$\left(\frac{740}{760 \times 100} = 0.00974 \right)$$

The total oxygen consumption is determined in the usual way just prior to the commencement of the rebreathing period. Then

Total O_2 consumption
Arterio-venous oxygen difference

= cardiac output in liters per minute

PHYSICAL METHODS

The *ballistocardiographic method* was originated by Henderson some years ago and has been elaborated and modified in recent years by Starr and his colleagues. The cardiac output is calculated from the record made by the recoil of the body caused by movements of the heart and blood in the opposite direction during systole. It involves the basic principle that "every reaction has an opposite and equal reaction." The apparatus or ballistocardiograph consists of a table suspended from the ceiling by wires and braced to prevent any but a horizontal movement in the long axis of the body. The patient lies supine on the table with his feet braced against a footboard. The movements of the table are opposed by a strong spring and magnified some 8,000 times through an optical recording system. The apparatus is calibrated by subjecting the table to a static force of 280 grams which causes the displacement by 1 cm. of the spot of light on the photographic surface. The normal ballistocardiogram shows three principal waves H, I, and J, inscribed during systole. Wave H is due to a small headward movement of the body and is caused by the movement feetward of the heart and of the blood within it, in the isometric period of systole (fig. 101 A). Wave I is due to a sharp recoil of the body feetward due to the ejection of blood into the aorta. The J wave is the result of a headward movement caused by the recoil of the aorta as the blood flows down the descending aorta. The stroke volume is calculated from the height of the waves, I and J, and by applying the following formula.

$$\text{Stroke volume} = 7\sqrt{[I + J]AC^{2/3}}$$

where A is the diameter of the aorta (calculated from age and surface area according to Bazett's data) and C the duration of the cardiac cycle; the minute volume is

obtained by multiplying the value of the stroke volume by the pulse rate.

Measurements of the cardiac output by the direct Fick method, which consists of sampling the mixed venous blood of the right auricle by means of a catheter introduced through an arm vein and of the arterial blood by arterial puncture, give values 18.5 per cent higher than those obtained by the ballistocardiographic method as just described, but when the figure for aortic cross section is obtained by a roentgenological method this difference is reduced to 3.5 per cent (Cournand and his associates).

The blood pressure method (as employed by Bazett and his associates). The stroke volume of the heart can be calculated if the following are known; (1) the volume

FIG. 101A

of the arterial vessels at the end of diastole, (2) the outflow from the arterial system during the cardiac cycle and (3) the distensibility of the arterial walls. The volume of the arterial system is calculated in sections—from commencement of aorta to the third part of the subclavian artery (\bar{V}_1) the descending aorta, with its iliacs and other branches except those nearer the heart than the subclavians (\bar{V}_2), the sections between the subclavian and the brachial at the elbow and including the other vessels of the upper part of the body with the same pulse wave velocities (V_3) and finally, the vessels of the lower limbs together with the vessels of the arms, splanchnic area and elsewhere having similar pulse wave velocities (\bar{V}_4). The values for \bar{V}_1 and \bar{V}_2 are obtained from tables giving the measurements in cadavers of different heights, surface areas and ages. The volumes \bar{V}_3 and \bar{V}_4 are assumed to vary with size of body but not with age, and are purely empirical, being

based upon the ability of the equations to give results which agree with those obtained by the acetylene method.

The distensibility of the arterial walls is determined from the pulse wave velocities (p. 150) in the different sections, recording tambours being placed upon the apex beat, subclavian, brachial, femoral, and dorsalis pedis arteries.

The outflow during diastole is determined from the change in volume of the arterial vessels from the peak of the diastolic wave to the end diastole. The volume change is estimated, in turn, from Bramwell and Hill's modification of Moen's equation, namely, *that the percentage of volume change per millimeter of mercury*

increases in pressure = $\frac{12.7}{v_1}$ where v_1 is the pulse wave velocity in meters per second. The outflow from the arterial system during diastole is then calculated from the equation

$$V_d = \frac{12.7(Z - D)}{100} \left(\frac{\bar{V}_1}{v_1^2} + \frac{\bar{V}_2}{v_2^2} + \frac{\bar{V}_3}{v_3^2} + \frac{\bar{V}_4}{v_4^2} \right)$$

where V_d is the outflow of blood during diastole, Z the diastolic pressure, and D the pressure at the end of diastole, V_1 to V_4 the volumes of the arterial sections already described and v_1 to v_4 the pulse wave velocities in these sections.

The outflow during systole (s period) must, of course, be taken into account. It is related to and derived from the volume leaving in the diastolic period (V_d) and calculated from the ratio of the mean pressures in the two periods. Thus,

$$V_s = V_d \times s/d \left(\frac{M_s - a}{M_d - a} \right)$$

where V_s is the volume of blood leaving the arterial system during systole, M_s and M_d are the mean pressures during systole and diastole; a is a constant having usually a value of 20 when the blood pressure is expressed in millimeters of mercury. The *stroke volume* (V) = $V_s + V_d$ and the *output of the heart per minute* (V_1) = $V \times F$, where F is the pulse rate.

The results of this method have been found to agree within less than 10 per cent with those of the acetylene method.

CHAPTER XXVII

THE CONTROL OF THE BLOOD VESSELS. THE VASOMOTOR MECHANISMS. PERIPHERAL VASCULAR DISORDERS. SURGICAL SHOCK.

The walls of the arterioles are composed chiefly of involuntary muscle fibers arranged in a circular fashion. Like the cardiac muscle the musculature of these vessels is supplied by two types of nerve fibers—inhibitory and excitatory. Those which cause contraction of the arteriolar musculature are called *vasoconstrictor*; those which inhibit, and in consequence cause relaxation of the muscular rings, are termed *vasodilator*. The former are therefore analogous to the cardiac accelerator (augmentor) nerves, and the latter to the vagi. Both sets together are referred to as the *vasomotor nerves*.

THE VASOCONSTRICTOR FIBERS

These were discovered in 1852 by Claude Bernard, who stimulated the cervical sympathetic nerve in the rabbit and observed constriction of the vessels of the ear. They belong to the thoraco-lumbar (sympathetic) division of the involuntary nervous system. The constrictor fibers arise from groups of nerve cells situated in the lateral horns of the cord, extending in man from the first thoracic to the second or third lumbar segment, inclusive. All the arterioles of the body wherever situated are supplied with filaments whose ultimate source is in this relatively limited region of the central nervous system. They are distributed to the periphery in the manner elsewhere described for the thoraco-lumbar outflow in general (see p. 936).

The vascular nerves of the limbs, as shown by Todd and Kramer and by Woollard, are distributed by two distinct modes. (1) A *proximal* innervation which arises in the case of the vessels of the upper limb directly from the cervical part of the sympathetic chain—middle and inferior cervical ganglia. The fibers pass to the subclavian artery and are conveyed in a plexiform manner along the outer coat of this vessel and its branches, and into the arm along the axillary artery. The corresponding supply to the vessels of the lower limb is derived by extension from the aortic plexus in the abdomen. The fibers follow the common and external iliac arteries into the thigh. The sympathetic fibers derived in the manner just de-

scribed do not extend beyond the larger vessels of the limbs—proximal portions of the brachial and femoral. (2) A *distal* innervation which is carried to the peripheral vessels via the somatic nerve trunks (e.g., ulnar, sciatic, etc., fig. 102). These reach the arteries at different levels and, penetrating the vascular wall, form a nerve net surrounding the muscular coat; the highest level of this type of innervation probably overlaps the region innervated by the proximal group of fibers mentioned above. The lowest levels supply the arterioles and capillaries. It is solely through such sympathetic fibers traveling with somatic nerve trunks that constrictor impulses are conveyed to the minute vessels of the limbs. Ganglion cells are absent from the vessels of the limbs. Section of a peripheral nerve, therefore, causes complete degeneration of vasoconstrictor fibers in the area of its distribution.

The existence of the distally distributed set of vasoconstrictor fibers has an important bearing upon operations designed to denervate the vessels. Periarterial neurectomy, for example, in which a segment of a main artery is stripped, will interrupt fibers belonging to the proximal set but will leave the distal supply to the vessels intact. Histological examinations of the peripheral vessels of limbs which had been amputated some time after periarterial neurectomy had been performed have shown only undegenerated nerve filaments.

Vasoconstrictor fibers to the head and neck are conveyed from the sympathetic chain through plexuses investing the blood vessels, but also via peripheral nerve trunks (cervical and certain cranial nerves). The vessels of the abdomen and pelvis are supplied with fibers which pass along the vascular walls from plexuses surrounding the aorta and its branches.

The vasoconstrictor fibers are non-medullated, but other fine medullated fibers may be detected ramifying around the peripheral vessels. These are afferent and convey sensory impulses (pain) from the vessels as well as dilator impulses (antidromic, p. 235) to the vascular muscle; they travel in the mixed somatic nerves and enter the cord

by the posterior spinal nerve roots. None degenerates after removal of the sympathetic chain.

Evidence has accumulated within recent years which indicates that vasoconstrictor, like certain

THE VASODILATOR FIBERS

The origins of the vasodilator fibers are more diverse than those of the vasoconstrictors. Dila-

FIG. 102. Origin of the vasoconstrictor fibers to the limbs and their distribution in the peripheral nerves. M.C.G., middle cervical ganglion; I.F.G., inferior cervical ganglion. Superior cervical ganglion and distribution of vasoconstrictors to head are not shown (see also p. 938). Preganglionic fibers, red; postganglionic, blue.

other sympathetic effects, are mediated through the liberation of an adrenaline-like substance at the nerve endings (see pp. 212, 691 and 946).

tor impulses emerge from the central nervous system by: (1) the *thoracico-lumbar outflow* the fibers of which reach a given vascular area by the

same route as that travelled by the vasoconstrictor impulses, (2) the *cranial outflow* of the parasympathetic division reaching the periphery via the *chorda tympani*, *glossopharyngeal* and the *vagus* nerves, (3) the *sacral outflow or pelvic nerve*, and (4) *the posterior spinal nerve roots—antidromic impulses*.

VASODILATORS OF THE THORACICO-LUMBAR DIVISION
(SYMPATHETIC)

The question of vasodilator fibers in the sympathetic has been debated, since most workers in the past doubted their existence. Several observations had, nevertheless, suggested such a distribution. Dastre and Morat, for example,

the dilators had apparently been unmasked when the stronger vasoconstrictor effect was annulled by the drug.

Burn produced further evidence for the presence of vasodilators in the lumbar sympathetic chain of the dog. After the blood pressure had been elevated (by the infusion of adrenaline) stimulation of this nerve caused vasodilatation and a fall in blood pressure.

The sympathetic vasodilators are of two types, namely, those which bring about their effect by the liberation of acetylcholine (*cholinergic fibers*, p. 950) and those whose action is mediated by an adrenaline-like substance (*adrenergic fibers*). The distribution of each type varies with the species and in different vascu-

TABLE 20
Distribution of vasoconstrictors (see also Chapter LXXIII)

REGION OF BODY	ORIGINS	
	Preganglionic fibers	Postganglionic fibers
Head	1st and 2nd thoracic segments of cord (man)	Superior cervical ganglion
Upper limb and neck .	3rd to 7th thoracic segments inclusive (man)	1st, 2nd and 3rd thoracic and inferior and middle cervical ganglia thence via nerves of brachial plexus
Lower limb	10th thoracic to 2nd lumbar segments	From 12th thoracic to 4th sacral ganglia thence via nerves of lumbo-sacral plexus
Thoracic aorta and branches	1st to 5th thoracic segments	Middle and inferior cervical and 1st to 5th thoracic ganglia
Pulmonary vessels . . .	2nd, 3rd and 4th thoracic segments	
Abdominal and pelvic viscera	6th thoracic to 3rd lumbar segments inclusive	Celiac, mesenteric and hypogastric ganglia (no cell stations on vertebral chain of ganglia)

observed flushing of the buccal mucosa upon stimulation of the cervical sympathetic; this observation was confirmed by others (Carlson, Langley). The phenomenon, however, was ascribed by Gaskill, Bayliss and others not to vasodilator impulses but to the liberation of vasodilator substances (CO₂, lactic acid, etc.) from neighboring small glands of the mucosa, excited by the stimulation of secretory fibers contained in the cervical sympathetic.

On the other hand, Dale showed that after ergotoxine, which abolishes secretory as well as vasoconstrictor and other motor sympathetic effects, stimulation of the splanchnic or of the abdominal sympathetic caused dilatation of the vessels of the intestine or of the leg, respectively. This was strong evidence for the existence of sympathetic vasodilator fibers. The action of

lar areas of the same species. In the dog and hare the muscles are plentifully supplied with sympathetic vasodilators of the cholinergic variety (Bülbring and Burn). Stimulation of sympathetic fibers to the muscle vessels of the dog after ergotoxine administration (which paralyses constrictor fibers) causes vasodilatation, the reaction being enhanced by eserine (physostigmine) and abolished by atropine. Moreover, a vasodilator response is obtained from the stimulation of sympathetic fibers if eserine has been administered previously, the action of the vasodilators now overbalancing that of the constrictors. There are only a few sympathetic vasodilators in the muscles of the cat and they are entirely adrenergic, the vasodilation caused by stimulation of the sympathetic after ergotoxine administration being unaffected by eserine or atropine. That cholinergic sympathetic vasodilators also innervate some vascular area in the cat is indicated by the experiments of Cannon and Rosenblueth who found that the

fall in blood pressure following stimulation of the abdominal sympathetic after ergotoxine was enhanced by eserine and reduced or abolished by atropine. The muscles of the monkey and of the rabbit receive no sympathetic vasodilator fibers of either kind. The skin of the dog, except over the ears, is devoid of sympathetic vasodilators. The presence of sympathetic vasodilators in the human skin is in dispute. The experiments of Lewis and Pickering seemed to have demonstrated the existence of such fibers, but Uprus, Gaylor and Carmichael in a later investigation have questioned the conclusions of the previous workers (see, however, Fatheree and Allan for affirmatory evidence).

ANTIDROMIC VASODILATOR IMPULSES

Stricker many years ago (1876-1877) reported that stimulation of the peripheral segments of the cut posterior roots of the sacral nerves caused dilatation of the vessels of the hind paw of the dog. This observation was at variance with the Bell-Majendie law which states that the posterior roots convey only centripetal impulses. Stricker's results were, consequently, not generally accepted. The question was studied afresh by Bayliss who showed in a series of carefully controlled experiments that Stricker's observation was essentially correct. Stimulation of the distal cut ends of the posterior roots of the 4th lumbar or the 1st sacral nerve, for example, was followed in every instance by dilatation of the vessels of the hind limb. Electrical, thermal and, especially, mechanical stimuli were effective. The effectiveness of the latter type of stimulus, which can be strictly localized, showed that the dilator response was actually due to the stimulation of posterior root fibers and not to the inadvertent stimulation of the anterior roots, as might occur with the use of an electrical type of stimulus (as a result of the escape of current). Furthermore, dilator effects in the vessels of the hind limb could be produced by stimulating the central end of an afferent nerve (such as the cardiac depressor, p. 240) after the abdominal sympathetic chain had been excised. This experiment shows that fibers of the posterior roots constitute the efferent limb of a depressor reflex.

There still remained the possibility, nevertheless, that *efferent fibers*, leaving the cord in the posterior roots, and not the ordinary sensory fibers were responsible for the dilator effect. Such a possibility was excluded, however, by sectioning the root between the ganglion and the cord and allowing time for degeneration to take place. Any efferent fibers would be cut off from their nerve cells by this operation and must, therefore, undergo degen-

eration. Afferent fibers, on the contrary, being still in connection with the cell bodies in the root ganglion would survive. Following the period allowed for degeneration, stimulation of the peripheral segment of the sectioned root caused the usual vasodilator response. On the other hand, when the section was made *distal* to the ganglion, stimulation of the distal stump after degeneration of the sensory fibers had occurred failed to cause vasodilatation. Trophic centers for the vasodilator fibers must, therefore, lie in the posterior root ganglia. The application to the ganglion of nicotine, which acts upon the synaptic junctions, did not abolish the vasodilator response when the posterior root was simulated on the central side of the ganglion. This fact indicates that the dilator fiber does not synapse within the ganglion. All the evidence points to the vasodilator fibers being derived from the ordinary bipolar ganglion cells, i.e., that they are identical with the afferent fibers of the peripheral nerves and posterior roots. In other words, the vasodilator impulses are conveyed along the fiber in a direction opposed to that in which the ordinary sensory impulses travel. For this reason they have been termed *antidromic* (running against) by Bayliss and Langley. Sherrington, from histological evidence, had also concluded that the posterior roots were free from efferent fibers. He sectioned the roots in monkeys and cats proximal to the ganglia and, after time had been allowed for degeneration to occur, examined the peripheral stumps for degenerated fibers; none was found.

Foerster, more recently, obtained cutaneous vasodilatation in man by stimulation of the posterior nerve roots at various levels of the cord. The vasodilatation had a segmental distribution.

According to Bayliss and Head, the sensory fibers which transmit the vasodilator impulses are those which subserve the sensation of pain (protopathic) and it was shown by Bayliss that in the case of the limb the antidromic impulses pass mainly to the vessels of the skin, few, if any, to vessels of the muscles. It appears that the vasodilator fibers of the posterior roots are distributed mainly if not entirely to the cutaneous and visceral vessels (the fibers to the latter travelling in the splanchnics). Bayliss observed that the limb deprived of skin showed only a slight increase in volume after stimulation of the appropriate posterior roots. The dilators to the vessels of skeletal and cardiac muscle, on the other hand, are derived from the sympathetic

(pp. 234 and 278). The vessels of skeletal muscle are therefore dependent upon the sympathetic for the transmission of both dilator and constrictor impulses. As compared with the skin and viscera, however, the muscular vessels rely to a greater extent upon metabolic products, carbon dioxide and lactic acid, for the control (p. 248) of their calibers. The vasodilatation which occurs in glands accompanying their secretion is also probably to a large extent due to the direct action of metabolites upon the vascular walls.

Antidromic vasodilator fibers homologous with those of the posterior roots are believed to exist also in certain cranial nerves, e.g., the trigeminal, which carried dilator impulses to the face and tongue (lingual). The conception of an antidromic vasodilator mechanism has far-reaching implications and has helped very greatly toward an understanding of several clinical phenomena hitherto inexplicable. Of these may be mentioned the vascular changes in certain diseases affecting the sensory side of the nervous system and the cutaneous lesions arising in tabes, especially along the course of the lightning pains. The blisters which occur in herpes zoster have been shown by Head and Campbell to be associated with lesions of the cells of the posterior nerve roots.

Within recent years the question of antidromic transmission of vasodilator impulses has been questioned by some observers who claim to have demonstrated the presence of efferent fibers in the posterior roots. The Japanese school, headed by Ken Kure, has referred to these fibers as constituting a "spinal parasympathetic system." This conception has not gained general acceptance. Quite recently, however, Kahr and Sheehan obtained evidence for the existence of efferent fibers in the posterior roots of cats. When the posterior roots from 12 thoracic to 2 lumbar were sectioned between the ganglion and the cord and time allowed for degeneration to occur, undegenerated fibers were found in the proximal stumps and degenerated fibers in the distal stumps. These, it was concluded, must have been derived from nerve cells situated within the central nervous system, and studies of sections of the cord revealed changes in the Nissl bodies of cells situated in the lateral and anterior horns ("retrograde" degeneration, p. 779). But, though the existence of efferent fibers in the posterior roots should be demonstrated conclusively by histological methods, it does not necessarily follow that they convey vasodilator impulses. The physiological experiments of Bayliss cited above furnish strong evidence that vasodilator impulses are transmitted antidromically in the posterior roots. Even if efferent fibers made connection with cells in the root ganglia (as is maintained by Kure, but which remains unproved) Bayliss' experiments could be ex-

plained, only in part, otherwise than by the antidromic hypothesis. Nevertheless, the conception of antidromic impulses has been a difficult one for physiologists to accept because it contradicts the Bell-Magenau law (p. 810). It is not possible to discuss the question here except in the most cursory manner. The reader is referred to a paper by Bishop and associates and to a recent article by Barron and Matthews. The former observers consider that the vasodilator fibers of the posterior roots, though having their cell stations in the posterior roots are efferent in function, and analogous to similar fibers in the vagus. Barron and Matthews find that certain fibers of the posterior roots, which from degeneration experiments apparently have their trophic centers within the cord, are in reality derived from posterior root ganglia situated at a lower level. That is, the sensory fiber after entering the cord and ascending for a short distance gives off collaterals which emerge in the posterior root of a higher spinal segment. When the posterior root is sectioned between the posterior root ganglion and the cord these collateral fibers must, of course, undergo degeneration distal to the point of section. The presence of such fibers may explain the findings of Kahr and Sheehan mentioned above. It is clear that the results of further investigation alone can lead to a complete elucidation of the nature of the vasodilator fibers in the posterior roots.

THE PELVIC NERVE (NERVUS ERIGENS) AND THE PHENOMENON OF ERECTION

The pelvic nerve is composed of fibers which leave the cord in the anterior roots of the 2nd, 3rd and sometimes the 1st and 4th sacral nerves. It conveys dilator fibers to the vessels of the penis or clitoris. The erectile tissue of these organs is composed of cavernous blood sinuses whose walls contain involuntary muscle. To reach these spaces the blood passes through arterioles and capillaries. The outlets from the sinuses are guarded by rings of involuntary muscle. Dilator impulses cause arteriolar and capillary dilatation coincident with inhibition of the involuntary muscle in the walls of the sinuses, and excitation of the muscle guarding their outlets. These effects cause dilatation of the vascular spaces, a high pressure within them, and, as a consequence, hardening and erection of the organ. There is also evidence that arterio-venous anastomoses (p. 273) also exist which open up to increase the blood flow into the erectile tissue. The narrowing of the venous outlets impedes the outflow from the sinuses only until the blood pressure within their cavities is raised to a certain height; then the outflow from the organ equals the inflow and the velocity of flow through the erectile tissue becomes greatly increased. This is evidenced by

rise in temperature and the bright arterial color of the blood flowing along the dorsal vein of the penis. The arterioles, capillaries and walls of the sinuses are also furnished with constrictor fibers, derived from the prostatic plexus (p. 941); stimulation of these nerves by reducing the blood flow through it cause shrinkage of the organ. The afferent pathway for the reflex of erection is through the pudendal nerves.

The constrictor center, occupies the apex of the ala cinerea or the fovea inferior. The second point—the vasodilator center—lies just lateral to the obex. Both centers are bilaterally represented. It is unlikely that these areas represent the highest centers of the vasomotor system. More recent work indicates that the latter are situated in the hypothalamus, and even in the cerebral cortex.

TABLE 21
Summary of vasodilator fibers (see also Chapter LXXIII)

REGION	ORIGIN	COURSE
	Parasympathetic (cranial outflow) Thoracico-lumbar outflow	7th, 9th and 10th cranial nerves. Cervical sympathetic cord
limb.....	6th, 7th, 8th cervical and 1st thoracic segments Thoracico-lumbar outflow probably from same segments as those giving rise to constrictors (p. 900)	Posterior roots of corresponding somatic nerves Probably same as vaso-constrictors
limb.....	5th, 6th and 7th lumbar 1st and 2nd sacral Thoracico-lumbar outflow probably from same segments as those giving rise to constrictors	Posterior roots of corresponding somatic nerves Abdominal sympathetic chain and somatic nerves
abdominal and pelvic organs.....	Thoracico-lumbar outflow probably from same segments as those giving rise to constrictors	Splanchnics
or clitoris.....	Parasympathetic (sacral outflow) 2nd, 3rd and 4th sacral segments	Anterior roots and nervi erigentes (pelvic nerves)

The pelvic nerve also sends dilator fibers to the walls of the rectum, descending colon and bladder.

THE VASOMOTOR CENTERS

The constrictor and dilator vascular effects are controlled by centers—the vasoconstrictor and vasodilator centers—situated in the floor of the 4th ventricle of the medulla. The constrictor center is also connected to a subsidiary center (or group of centers) in the cord. This is constituted of the cells in the thoracico-lumbar region of the medulla already mentioned (p. 232). Ranson and Langley explored the floor of the 4th ventricle by means of a needle electrode and located two points which when stimulated caused respectively a rise or a fall in blood pressure of from 30 to 40 Hg. The former point, which probably

VASOMOTOR TONE AND ITS REGULATION

The constrictor center exhibits tone. It is generally stated that dilator tone is absent, but Bayliss has shown that this exists to a slight degree, under certain circumstances at any rate. Dilator tone is much more difficult to demonstrate since constrictor and dilator fibers in most instances run together and the effects of the former mask those of the latter. The tone of the vasoconstrictor center may be demonstrated by sectioning the cord in the lower cervical region. This interrupts the stream of impulses passing from the medullary to the spinal centers, the vessels dilate and the blood pressure falls. After a time, however, the blood pressure rises again; the spinal centers exhibit their inherent power of autonomous action, and assuming the duties hitherto exercised

by the medullary centers, restore the vessels to their previous state of tonic constriction. The time required for the vessels to regain their tone after section of the cord varies considerably in different species (see spinal shock, p. 828).

The high degree of vasoconstrictor tone which is normally maintained is shown by the fact that section of the splanchnics doubles the flow in the vessels of the denervated area (Burton-Opitz). A corresponding increase in the flow through the femoral artery after removal of the lumbar sympathetic has been demonstrated by Herrick, Essex and Baldes; the greater flow persists for several months.

After the tone resulting from cord section has been restored it falls again if the splanchnics are sectioned, but after a time a certain degree of tone is regained. This resides in the vascular muscle itself—*peripheral tone*. Apparently, a long period is required for the development of the intrinsic arteriolar tone. Essex and his associates found that, nearly eleven months after its denervation, the flow in the dog's femoral artery was double that in the opposite femoral. But nine years after the operation, the flow was almost equal on the two sides. Examination of the small vessels of the denervated side showed pronounced hypertrophy of the muscular coat. The vessels of this side were also especially susceptible to the constrictor action of adrenaline (see p. 686).

The tone of the vasomotor center is dependent (1) upon afferent nerve impulses received from various organs and regions of the body as well as from other nervous centers (cerebral cortex, respiratory center etc., see p. 245) and (2) upon the chemical composition of the blood.

VASOMOTOR REFLEXES

Vasomotor reflexes can be elicited by the stimulation of practically any afferent nerve—somatic or visceral.

VASCULAR REFLEXES RESULTING FROM THE STIMULATION OF SOMATIC NERVES

Stimulation of the central end of a nerve such as the *sciatic*, the *median* or a sensory *cranial* nerve may result in either a rise or a fall in the arterial blood pressure according to the strength and type of the stimulus employed. An elevation or depression of the blood pressure brought about in this way is spoken of, respectively, as a *pressor* or a *depressor reflex*. The components of the reflex arc upon which the responses depend are, (1)

afferent fibers in the peripheral nerve, (2) the vasomotor centers, and (3) the efferent vascular nerves, i.e., the vasoconstrictors or vasodilators.

FIG. 103. Effect of stimulating somatic nerves upon arterial blood pressure. Upper tracing shows rise in carotid pressure during faradic stimulation of the central end of the brachial nerve of cat. Lower tracing shows fall in blood pressure as a result of stimulating the central end of the sciatic nerve. (After Ranson and Billingsley.)

In order to elicit the pressor reflex, a stimulus much stronger than that necessary to provoke the depressor response must, as a rule, be applied, that is, one which would elicit pain in a conscious animal. Stimulation of the cornea which is supplied liberally with pain fibers gives a definite pressor response. In a series of experiments by

Ranson and Billingsley, the pressor response ranged from 8 to 45 mm. Hg and the depressor from 4 to 22 mm. Hg (fig. 103). In the elicitation of either reflex the magnitude of the response is apparently dependent upon the number of afferent fibers involved. For example, stimulation of various nerves of the brachial or lumbar plexus caused practically equivalent depressions or elevations in the blood pressure when the number of afferent fibers in the respective nerves was taken into account. It has also been shown by Martin and Stiles that similar reflex effects evoked simultaneously from separate afferent nerves are summed; dissimilar reflexes are mutually antagonistic.

It has been thought that these contrary effects upon the blood pressure were dependent upon two corresponding types of specific afferent fibers—pressor and depressor—in the peripheral nerve. The fact that stimuli of different intensities and frequencies caused opposite effects seemed in itself to imply the presence of two sets of fibers, one with a higher threshold than the other. Weak, slowly repeated stimuli are more likely to cause a fall, strong rapidly repeated stimuli a rise in blood pressure. Other observations seemed to point to the existence of two separate sets of fibers. After cooling the nerve, or sectioning it and allowing a certain period to elapse, the depressor effect could be obtained but not the pressor. The pressor fibers were presumed to degenerate before the depressor. Again, depressor reflexes are obtained more readily from cranial nerves, whereas the usual response to stimulation of the central end of a spinal sensory nerve is a pressor response, which suggested that different nerves contain the respective types of afferent fibers in varying proportions. The work of Ranson and Billingsley indicates that the pressor fibers are not specific but are identical with those which subserve protopathic sensibility (pain, extremes of temperature, p. 803), whereas the depressor fibers correspond to those which transmit sensations of touch or warmth. According to Ranson the fibers transmitting *pressor* are unmyelinated and enter the cord in the lateral division of the posterior roots. Their intraspinal course is by short internuncial fibers in the tract of Lissauer, the nerve cells lying in the gray matter of the tip of the posterior horn. An experimental lesion, involving this pathway on both sides of the cord in the lumbar region or of the lateral divisions of the posterior roots, was shown by Ranson and his associates to abolish the pressor reflex usually obtained by stimulation of the sciatic. The depressor reflex remained unaffected. The intraspinal part of the *efferent* limb of the pressor reflex lies in the anterior or the lateral column of the cord. The impulses (vasoconstrictor), as mentioned elsewhere, leave the cord by the white rami. In support of the conclusion that the pressor fibers are identical with those mediating proto-

pathic sensibility, Bayliss and Head observed that after section of a peripheral nerve, the pressor reflex (but not the depressor) could be elicited from the regenerating nerve at the time when protopathic sensibility was returning. The association of pressor responses with painful sensations points to their being an integral part of the defensive mechanisms (nociceptive reflexes, adrenaline liberation, etc.).

After entering the cord by the posterior roots the *depressor* impulses ascend in that part of the lateral column occupied by the spino-thalamic tracts. But they are not identical with the fibers of the latter since they end in the medulla (vasodilator center). Bilateral section of this part of the lateral column abolishes the depressor reflex; the pressor reflex becomes more pronounced which suggests that ordinarily it contains a masked depressor element. The intraspinal *efferent* limb of the depressor reflex (vaodilator) is unknown.

It must be mentioned that not all the pressor or depressor impulses ascend to the medulla but that reflex arcs exist having their centers within the cord; both vasoconstrictor and vasodilator reflexes can be elicited in an animal whose cord has been divided in the lower cervical region a short time previously.

Pressor and depressor reflexes can be readily elicited in man by peripheral nerve stimulation. Warmth, for instance, applied to the feet or other part of the body causes vasodilatation in other parts remote from the point of application and a fall in pressure may result. If, however, the applied temperature is raised to the point where it becomes painful, reflex vasoconstriction occurs. The application of cold also usually produces the latter effect. The vasodilatation in one extremity resulting from the immersion of another in warm water is not due to the stimulation of afferent endings in the heated tissues, but to the warmed blood acting upon a nervous center; through this and the efferent nerves the vasodilatation is brought about. Gibbon and Landis, for example, showed that the vascular response was abolished by occluding the circulation of the heated member and that it could be produced in the hands of a subject with complete transection of the cord by warming the feet. The response to cold is due in part to afferent impulses and in part to the effect of the altered temperature of the blood returned from the cooled member upon the nervous center. A change in temperature (a rise or fall) of the tissues of from 0.01 to 0.04°C. is sufficient to induce the vascular response. Other interesting reflex vascular reactions must be mentioned. Mudd and Grant showed that a

draught directed to the bare back or arm caused constriction of the vessels of the pharynx and nasal mucosa. Constriction of the vessels of the bronchi as a result of the application of cold to a remote part of the body has also been observed by means of the bronchoscope. On the other hand, deep inspiration causes reflex constriction of the cutaneous vessels. From the results of experiments upon animals it is to be expected that in the human subject a painful stimulus applied to a somatic nerve will be followed by a pressor response. The excitation of psychic centers, and also the liberation of adrenaline are additional factors which play an important part in the pressor response resulting from painful stimuli. On the other hand, stimulation of the mesentery, peritoneum and abdominal viscera or of certain regions such as the anus, vagina and spermatic cord is usually followed by a fall in blood pressure. Bayliss demonstrated a fact of some practical importance, namely, that pressor reflexes become depressor in character under chloroform anesthesia; this reversal was not observed when ether was employed. Strychnine tended to annul the effect of chloroform and to convert depressor reflexes into those of the pressor type.

VASCULAR REFLEXES MEDIATED THROUGH AFFERENT FIBERS OF THE VAGUS

In the section dealing with the reflex control of the heart rate it was mentioned that the vagus contains afferent fibers which terminate in the aortic arch and heart. Stimulation of these fibers also produces alterations in the caliber of the blood vessels and, as a result, changes in blood pressure. In some instances, electrical stimulation of the cerebral stump of the severed vagus is followed by a rise in blood pressure (pressor reflex); more usually, however, a fall in pressure occurs (depressor reflex).

Vagopressor reflexes

The pressor fibers of the vagus are stimulated by a fall in the pressure of blood in the great veins emptying into the right auricle. McDowall, confirming an old observation of Pavlov's, found that when the venous pressure was lowered by hemorrhage (or by the intravenous injection of alcohol or of histamine) no change or a moderate decline in the arterial pressure occurred so long as the vagus nerves were intact. When, however, these nerves were severed, a fall in arterial pres-

sure occurred if this had been unchanged prior to the nerve section, or a further fall resulted if the arterial pressure had been already lowered coincidentally with the fall in venous pressure. These observations have been confirmed by Anrep and Segall. Cocainization of the auricle has the same effect as vagotomy. It is concluded from these results that the fall in venous pressure exerts an influence upon afferent vagal endings situated in the right auricle; messages ascend to the medullary centers and cause a generalized vasoconstriction. This reflex is probably responsible in part for the vasoconstriction which occurs as the usual response to hemorrhage and surgical shock (p. 258), both of which conditions are associated with a fall in venous pressure.

It has also been shown by McDowall that a rise in venous pressure considerably above the normal level calls forth a vagopressor reflex, as evidenced by the vasoconstriction which occurs in a limb connected to the body solely by its nerves, when saline is injected into the inferior vena cava. This reflex occurs coincidentally with and is supplementary to the Bainbridge reflex (cardiac acceleration, p. 209). It antagonizes the depressor reflex elicited from the aortic nerve or carotid sinus and McDowall suggests that through its predominance over the latter reflexes (see below) the elevation of the arterial pressure is permitted to persist throughout muscular exercise.

The aortic or cardiac depressor nerve

In certain animals (e.g., the rabbit) the vagal fibers mediating the depressor response of this nerve are collected into a separate nerve which arises from the trunk of the vagus high in the neck. This branch of the vagus which is known as the *aortic or cardiac depressor nerve* was first described by Cyon and Ludwig (1866). It is purely afferent and depressor in function; when sectioned and its central (cerebral) end stimulated a pronounced fall in pressure occurs (fig. 104); excitation of the cardiac end, on the other hand, causes no effect. Two factors are involved in the depressor response following stimulation of the depressor fibers (whether these are contained within the vagus itself or are segregated in the aortic nerve); (1) *slowing of the heart rate and increased force of the ventricular contraction*. The efferent fibers of the vagus of the same and of the opposite side constitute the efferent limb of the reflex arc through which this response is brought about (p. 205); for its elicitation at least one vagus must, therefore,

remain intact. (2) *Vasodilatation*. The vasomotor pathways constitute the efferent limb of this reflex. Vasoconstrictor tone is reduced and vasodilator tone increased. The reflex effect upon the vessels cannot, therefore, be elicited after section of the spinal cord in the lower cervical region.

The receptors of the reflex (i.e., the terminals of the aortic nerve) are situated in the aortic arch and upper part of the thoracic aorta, in the ventricles and probably also, according to Daly and Verney, in the coronary and pulmonary vessels (see fig. 106).

The fall in pressure is due mainly to dilatation of the splanchnic vessels. The dilatation is not, however, confined to these vessels but includes

FIG. 104. Fall in arterial blood pressure resulting from stimulation of the central end of the cardiac depressor (aortic) nerve. The drum was stopped in the middle of the curve and the excitation maintained for seventeen minutes. The line of zero pressure should be 30 mm. lower than here shown. (From Bayliss.)

those of the skin and muscles. Cardiac slowing plays a minor rôle in the production of the fall in blood pressure, for almost as great an effect can be obtained after both vagi have been cut. The depressor reflex can be elicited by mechanical or electrical stimulation of the aortic wall itself wherein the special proprioceptors are located; stretching is an especially effective type of stimulus. It was also shown by Einthoven and subsequently by several other observers that action currents ascend the nerve synchronously with the heart beats. The normal stimulus is, therefore, quite evidently the pulsatile expansion of the aortic wall, a rise in general blood pressure increasing the intensity of the stimulus, a fall in pressure causing the reverse effect. A small structure (*glomus aorticum*) analogous to the carotid body (see footnote p. 242) is connected with a branch of a fine artery arising from the aorta beyond its arch. The chemoreceptors of this structure

respond to oxygen lack. Reflex vasoconstriction and a rise in blood pressure follow their stimulation by anoxemia or by such drugs as cyanide, lobeline, nicotine, sodium sulphide and acetylcholine.

THE CAROTID SINUS MECHANISM.

(SEE ALSO P. 346)

The carotid sinus is the term applied to the slight enlargement of the common carotid artery where it bifurcates into the internal and external carotids (fig. 105). The dilatation usually involves, as well, the commencement of the internal carotid, or may be confined to this region. The

FIG. 105. Showing the carotid sinus region in man (after Heymans). 1, common carotid; 2, carotid sinus; 3, internal carotid; 4, external carotid; 5, nerve to carotid sinus; 6, glossopharyngeal nerve.

carotid sinus was shown by Hering in 1923 to play an important rôle in the regulation of the cardiac rate and arterial blood pressure.¹ Compression of the carotid at its bifurcation (so as to raise the pressure within the sinus) caused a marked slowing of the heart rate, vasodilatation and a fall in blood pressure; these effects result though mechanical stimulation of the vagus is carefully avoided. Electrical stimulation of the sinus wall produced similar effects. Pressure upon

¹Sollmann and Brown were the first to describe a depressor reflex of this nature. They sectioned the carotid and obtained a fall in blood pressure when traction was made upon its cephalic end. They showed that the reflex was not affected by section of the vagus but was dependent upon nerve terminals in the wall of the internal carotid.

the common carotid some distance below the sinus (so as to reduce the pressure within the sinus) causes cardiac acceleration, vasoconstriction and a rise in arterial pressure together with, as shown by Heymans, the liberation of adrenaline. The carotid sinus therefore constitutes a mechanism whereby both pressor and depressor effects are mediated. The effects are brought about through the following neural mechanism.

THE SINUS REFLEX ARC. The afferent fibers of the reflex arc are contained in the *sinus nerve*,

FIG. 106. a branch of the glossopharyngeal. This delicate filament descends between the internal and external carotids to the sinus where its fibers terminate in sensory organs (proprioceptors) situated between the connective tissue fibers in the adventitia of the sinus wall. Fibers also ramify in the carotid body (*glomus caroticum*),² a small

²This structure known also as the *carotid gland* or *intercarotid body* is composed of rounded clumps of polyhedral cells, and possesses a rich network of capillaries of a sinusoid character. Some of the cells stain brown with chromic acid (chromaffin cells, p. 684). The intercarotid body however, does not contain adrenaline, and it is not believed to be an endocrine gland. It is a sensory organ containing chemoreceptors sensitive to changes in the oxygen

structure situated upon a branch of the occipital artery or upon a small vessel arising directly from the external carotid just above the bifurcation of the common carotid. Centrally the fibers of the sinus nerve make connections with the cardio-inhibitory and vasomotor centers. The efferent limb of the cardiac part of the reflex is, of course, the vagus. The efferent limbs of the vasodilator and vasoconstrictor reflexes are apparently sympathetic fibers, for these reflexes are abolished by complete removal of the sympathetic chains. As will be seen from figure 106, a nerve twig connects the sinus with the ganglion of the

FIG. 107. The upper curve in each record represents the arterial blood pressure registered by a membrane manometer; the lower curve of each record shows the electrical discharge from a single fiber of the carotid sinus nerve of the rabbit. In the upper record (A) the mean arterial pressure was 55 mm. Hg.; even at this low level a discharge of 4 impulses accompanied each ventricular systole. In the lower record (B) the mean arterial pressure was 135 mm. Hg.; in this instance there was a larger and more continuous discharge from the end organ. (Bronk and Stella.)

vagus; it also receives a filament from the superior cervical ganglion of the sympathetic.

The action currents passing along the sinus nerve have been studied by Bronk and Stella and by Partridge. Electrodes were placed upon the nerve and after amplification the potential changes were recorded by means of the oscillograph. At ordinary arterial

tension of the blood and through which reflex changes in respiration are effected (see p. 346). According to Comroe, this body plays little or no part in the control of the circulation. Others, however, (Heymans, Bernthal) claim that through these receptors, as through those in the aortic body, anoxemia or CO₂ excess causes reflex vasoconstriction and a rise in blood pressure.

pressures impulses are discharged throughout the cardiac cycle, their frequency increasing during systole and decreasing during diastole. Following the chief burst of rapid impulses which synchronizes with the main wave of the pulse tracing, a second rise in frequency occurs coincident with the dicrotic wave. A rise in general blood pressure increases the rate of impulse discharge as well as the number of sense organs excited. The latter show slow adaptation (p. 807) so that though the stimulus (distension of the arterial wall) persists the impulse discharge shows little reduction in frequency and when the pressure is very high they extend with little reduction in rate throughout diastole. Bronk and Stella were successful in recording the impulses from a single nerve fiber (fig. 107). The frequency of the impulses rises with increased pressure. At low pressures, impulses are discharged only during systole; but at high pressures they continue throughout diastole. The rate of impulse discharge was found to range according to the height of the arterial pressure from 5 to 140 per second.

The sinus reflexes have been studied exhaustively by Heymans and his associates. They carried out cross-circulation experiments which speak conclusively for the physiological importance of these reflexes in cardiovascular regulation (see fig. 108). The sinus of one dog (B) was isolated from the general circulation and perfused with the blood of another animal (A) in the manner shown in the figure. The nerve supply to the sinus was left intact. When the arterial pressure of dog A was raised, that of dog B, recorded in the femoral artery, fell. Conversely, a reduction in blood pressure of dog A caused a rise in the blood pressure of dog B. In the latter instance, adrenaline liberation also occurred which was a contributory factor in the blood pressure elevation. These effects could not be obtained after denervation of the sinus.

The sinus and aortic nerves, or so-called "buffer" nerves, constitute a mechanism of the utmost importance in controlling the arterial blood pressure and in maintaining the circulation to the brain. The rise in diastolic pressure and the increase in heart rate which occur when the body changes from the recumbent to the sitting position or from the sitting to the standing position, are apparently brought about through these nerves; they therefore play an essential part in compensating for the effect of gravity upon the circulation.

An underfilled state of the vessels, as may result from hemorrhage or shock, or any other condition which tends to cause a fall in blood pressure, will call these mechanisms into play. A general-

ized vasoconstriction results to adjust the vascular capacity to the reduced blood volume and thus maintain the blood pressure. Excessive elevation of the blood pressure, on the other hand, is count-

FIG. 108. (After Heymans.)

ered by a depressor reflex (see diagram fig. 109). The great importance of these reflex mechanisms in hemorrhage is shown by the fact that in an animal in which all four buffer nerves have been sectioned the rapid loss of only about $\frac{1}{10}$ of the blood volume proves fatal, whereas usually a reduction in blood volume of from 35 to 45 per cent is required to cause death. Mayerson found that tilting anaesthetized dogs from the horizontal to the upright position caused a sharp drop in blood pressure followed within 10 seconds by a compensatory rise. After section of both sets of buffer nerves the compensatory rise did not, as a rule, occur.

The cardiovascular effects are brought about through alterations in the frequency of the im-

pulses which are constantly ascending along the aortic and sinus nerves to the cardiac and vasomotor centers. Any increase in the tension exerted upon the proprioceptors in the sinus or aortic wall causes a rise in the frequency of the afferent impulses and, as a consequence, slowing of the heart and vasodilatation. It has been demonstrated by oscillographic methods that during a depressor reflex *efferent* impulses dis-

Several European workers (Hering, Heymans and Bouckaert, and others) have reported the occurrence of permanent hypertension in animals following bilateral section of the sinus aortic nerves. Pressures as high as 200 mm. Hg over a period of three years have been reported. Other investigators who have carried out similar experiments find that the hypertension so produced is not permanent in the majority of animals, but

FIG. 109. Diagrammatic representation of cardiovascular reflex mechanisms. Afferent vagal fibers in blue, sinus nerve in green, efferent fibers to the heart and to the blood vessels in red. The afferent fibers are represented as causing reciprocal effects upon the medullary centers (see also p. 245 and fig. 111).

charging over the cardiac accelerator and vasoconstrictor nerves are reduced in frequency or may cease. Reduction in the tension upon the vascular wall, on the other hand, by lessening the intensity of the stimulus to the nerve endings, lowers the frequency of impulse initiation and lessens the tonic depressor effect; a rise in arterial blood pressure results. The rise in blood pressure and increase in heart rate which occur during ether anesthesia, are attributed by Heymans and his associates to depression of the activity of the sinus receptors.

tends to return to normal after a variable period. Such a result may be due to the regeneration of the sectioned nerves or to the reflex control of the circulation being assumed by some other mechanism.

The carotid sinus in man

It is a very old observation that pressure upon the carotid artery in the human subject may cause slowing of the heart (Parry, 1799). Many of the examples in the literature of bradycardia due presumably to pressure upon the vagus were

in all likelihood due to a sinus reflex. Indeed it is very questionable whether the vagus can be stimulated by pressure through the overlying tissues, for in operations upon the neck, even pinching the nerve with forceps does not stimulate it; and in animals, the vagus is relatively unresponsive to mechanical stimulation.

Since the discovery of the carotid sinus, many observations upon the depressor reaction in man have been reported. In paroxysmal tachycardia the rate may often be restored temporarily to normal by the application of pressure to the sinus. Weiss and his associates have shown, however, that the sensitivity of the sinus reflex varies considerably in different individuals. In about 30 per cent of persons with normal cardiovascular systems no response whatever could be obtained. In the remainder the cardiac slowing amounted to less than 6 beats per minute and the fall in blood pressure to less than 10 mm. Hg.

HYPERSENSITIVITY OF THE SINUS (DEPRESSOR) REFLEX. In hypertension and arteriosclerosis the reflex is often unusually sensitive. In from 70 to 78 per cent of cases of hypertension observed by Weiss and Baker, a fall in arterial pressure of from 10 to 105 mm. Hg (average 40 mm.) and a reduction in heart rate of from 4 to 20 beats followed pressure upon the sinus. In a corresponding proportion of arteriosclerotic cases a fall of from 10 to 65 mm. Hg and an average reduction in heart rate of 16 beats per minute resulted.

These observations lend no support to the idea that a failure of the depressor sinus reflex as a result of structural changes in the sinus wall is a factor in the production of essential hypertension. As a matter of fact, marked changes in the walls of the sinus may occur with a normal blood pressure while hypertension may exist though the sinus shows no abnormality.

THE CAROTID SINUS SYNDROME (VASOVAGAL SYNCOPE (LEWIS)). Attacks of dizziness and fainting and sometimes convulsive seizures may result from overactivity of the sinus reflex. An attack may occur without known cause, be induced by emotion or follow slight pressure upon the neck. In one case which has been reported, shaving the skin of the neck overlying the sinus or buttoning a tight collar precipitated an attack. During an attack, marked slowing of the heart and a fall in arterial pressure occur. Extrasystoles, delay in A-V conduction, complete heart block or typical Stokes-Adams attacks may occur. In subjects of these paroxysms hypersensitivity of the sinus mechanism can usually be demonstrated between attacks, slight pressure producing

a pronounced depressor reaction (see fig. 110). In some of these cases no structural abnormality of the sinus is evident, the condition, apparently, being purely functional in nature; in others the sinus shows an aneurysmal dilatation; and in others again, a small tumor in the region of the carotid bifurcation has been responsible. In any event denervation of the sinus relieves the condition. After denervation, the blood pressure rises and the heart rate increases for a few hours but soon returns to normal.

BALANCED AND RECIPROCAL VASCULAR REACTIONS

In the intact animal the height of the blood pressure at any moment, insofar as the nervous control of the peripheral vessels is concerned, is

FIG. 110. The effect on blood pressure and heart rate of pressure on the carotid sinus (hypersensitive) in the human subject. Note that both blood pressure and heart rate show a marked fall immediately after stimulation of the sinus. When the pressure is released, the heart rate returns to normal very quickly, the blood pressure more slowly. (After Weiss and Baker.)

apparently the algebraic sum of the effects of afferent impulses impinging upon the vasomotor centers. Under ordinary circumstances impulses arising from the carotid sinus and aortic arch play the most prominent rôle, but impulses from skin, muscles and viscera and from higher nervous centers also exert an important influence. That pronounced effects upon the peripheral vessels can be produced by the irradiation of impulses from higher centers is evidenced by such phenomena as blushing, pallor, erection and certain types of syncope (fainting). The vascular changes observed by Drury and Florey in the mucosa of the exteriorized colon of the dog when the animal was excited; and the changes in splenic volume noted by Hargis and Mann and by Bar-

croft (p. 54) are other examples. Even very mild excitation of psychic centers exerts an influence upon the vascular mechanisms. The psychogalvanic reflex (due to changes in the electrical resistance of the skin) has a vascular basis. A reciprocal relationship also exists between splanchnic and cutaneous vascular areas on the one hand and the vessels of the muscles on the other. Adrenaline, for example, causes dilatation of the latter vessels accompanied by vasoconstriction in the skin and abdominal viscera. Stimulation of the wall of a large vein or distension of the duodenum causes reflex constriction of the cutaneous vessels and stimulation of the skin results in

dilate. Messages pass to the vasomotor center which then discharges vasoconstrictor impulses to the vessels of the area from which the afferent impulses arose. Thus, undue distension of the vessels and pooling of blood in the splanchnic region is prevented. It has also been shown by Izquierdo that stimulation of the peripheral end of the splanchnic nerve causes a much greater rise in blood pressure than usual if the carotid sinuses have been excluded from the circulation (by clamping the carotids). This observation indicates that ordinarily the pressor effect of splanchnic stimulation is largely counteracted by a depressor reflex initiated from the sinus.

FIG. 111. Illustrating the reciprocal action of the centers in vascular reflexes. A, vasoconstrictor center; B, vasodilator center.

an increase of the blood in the liver and in the renal cortex. Furthermore, the muscular and cutaneous tissues may show opposite vascular reactions. Thus, in the dog, cooling of the body causes constriction of the skin vessels and vasodilatation in the muscles; in man, adrenaline causes constriction of the digital arteries and dilatation of vessels of the muscles.

An interesting example of the complex nature of the reflex vascular adjustments has been described by Bronk and Gammon. An electrical record obtained from a twig coming from a Pacinian corpuscle in the mesentery during perfusion of the mesenteric vessels showed an increase in the frequency of the afferent impulses when the perfusion pressure was raised. The impulse frequency was reduced by bleeding the animal and increased again when the blood was reintroduced into the body. It is suggested that the Pacinian corpuscles which lie in close relation to the vessels are stimulated when the latter

Löwen reflex

This is the term applied to the reaction first described by Löwen, in which a local dilatation of vessels accompanies a general vasoconstriction. When, for example, the central end of an afferent nerve to an organ is stimulated while its efferent vasomotor fibers remain intact, a rise in general blood pressure occurs together with a dilatation of the vessels of the organ. It is evident that in the intact animal such a mechanism, brought into play through afferent impulses arising within the organ itself, will provide it with an increased blood flow during activity.

The reciprocal action of the medullary centers

The experiments of Bayliss and others indicate that the reflex vasomotor effects involve both centers in a reciprocal manner. In the depressor reflex the tone of the vasodilator center is raised while that of the vasoconstrictor center is lowered. Conversely, the vasodilator center is depressed and the vasoconstrictor center excited in a pressor reflex. These reciprocal reactions are shown diagrammatically in figure 111.

It has been generally conceded that in a depressor reflex, loss of constrictor tone is accompanied by increased tone of the vasodilator center. It is also granted, of course, that in a pressor reflex the vasoconstrictor center is stimulated; that depression of vasodilator tone accompanies the constrictor effect but not always been so apparent. The following experiment of Bayliss shows that the latter reaction also occurs. The vessels of the salivary gland were maximally dilated by means of heat and deprived of the constrictors by sectioning the cervical sympathetic. A pressor reflex elicited by stimulating the afferent end of a somatic nerve then resulted in a reduction in blood flow through the gland, which was ascribed to a reduction in vasodilator tone.

VASOMOTOR REACTIONS DURING MUSCULAR EXERCISE

Constriction of the splanchnic vessels occurs at the commencement of muscular exercise. This is attributed to the reception by the medullary centers of impulses discharged from the motor and psychic areas of the cerebral cortex. It is said that splanchnic vasoconstriction actually anticipates the commencement of the muscular effort and may even occur at the thought of taking exercise, though no actual movement is made. If the muscular effort is very strenuous, a rise in hydrogen ion concentration may occur and act as a stimulus to the vasomotor center. In ordinary exercise, however, no appreciable change in reaction of the blood as a whole occurs and even in the more severe types of muscular exertion a change in blood reaction is of minor importance in the production of the splanchnic vasoconstriction. The small vessels of the muscles dilate during exercise but this, as described on page 249, is a direct action upon the vessels of substances produced in the muscles themselves; though it is possible that the nervous centers do play a part in this reaction there is no evidence for this. The arterial blood pressure is highest in the earlier periods of the exercise when the systolic level may reach a height of 180 mm. Hg or more. Vascular readjustments, e.g., cutaneous vasodilatation and possibly a reduction in the degree of splanchnic vasoconstriction, tend to occur as the exercise continues; some reduction in the blood pressure results. Within 10 seconds or so after the cessation of the exercise, the pressure falls to normal but rises abruptly again to its previous level, then gradually declines and finally reaches the normal value in from one to four and a half minutes. These fluctuations in the arterial blood pressure following the exercise are not, however, of nervous origin but are due to mechanical factors (see p. 127).

An interesting reflex mechanism in the hypertension of exercise has been demonstrated in the human subject by Alam and Smirk. Contractions of even a small group of muscles, e.g., those moving the little finger, while the circulation through the arm was arrested, caused a rise of as much as 70 mm. Hg. Cerebral influences cannot be mainly responsible for the rise since it persisted, provided that the arm circulation was occluded, for some time after the exercise had ceased. Any effect of muscle metabolites upon the nervous centers is, of course, excluded since none could enter the general circulation. For the same reason increased

venous return to the heart cannot be a factor in the pressor effect. Arrest of the circulation alone was ineffective. The phenomenon, like the reflex acceleration of the heart (p. 210), is apparently due to the stimulation of afferent endings in the muscles by metabolites accumulated as a result of the circulatory arrest. Of how much importance such a reflex is in ordinary exercise, i.e., with free circulation through the muscles, it is difficult to say.

The effects of exercise upon other physiological functions are dealt with in other sections of this book. The reader is referred to the index under Muscular exercise.

AXON REFLEXES

These are not true reflexes, since no nerve cell is involved. The efferent and afferent limbs of the axon reflex arc are formed by the branching

FIG. 112. Axon reflex. Description in text.

of a single nerve fiber. A stimulus applied to one branch sets up an impulse which travels centrally to the point of division from where it is reflected down the other branch to an effector organ. The most familiar type of axon reflex is that which involves a sensory nerve fiber and through which vasodilator effects are brought about. Ninian Bruce has made a study of the superficial vasodilatation which results from cutaneous or conjunctival stimulation, and offers convincing evidence for the dependence of these reactions upon axon reflexes. Spiess had remarked some years before that in inflammatory states of the superficial tissues the more painful the part became, the greater was the development of heat and redness. The degree of dilatation of the vessels seemed to be dependent upon and directly proportional to the pain experienced. A local anesthetic reduced the pain and the inflammatory reaction as well. Bruce found that the dilatation of the vessels which results from the application of an irritant, such as mustard oil,

to the conjunctiva of an animal can be prevented if the sensory nerve endings are first paralyzed by means of cocaine (or better, alypin, which has no direct effect upon the vessels). On the other hand, if the mustard oil be applied shortly after division of the fifth nerve, which also renders the conjunctiva insensitive, the usual inflammatory reaction occurs. Yet if sufficient time be allowed to elapse after division of the nerve for degeneration of the sectioned sensory fibers to take place, the conjunctival reaction to irritants cannot be elicited. Corresponding results were obtained in experiments upon the skin of the trunk. The employment of a local anesthetic abolished the reaction. It was obtainable after section of the posterior roots peripheral to their ganglia, so long as degeneration of the sensory fibers had not occurred, but was abolished after this. The vasodilator reactions cannot, therefore, be due to a central reflex, yet they are dependent upon the integrity of the sensory nerve fibers. Since no peripheral nerve cells are known to exist through which such a reaction could occur, the latter must, it is concluded, be due to an axon reflex. The impulse evidently passes up a sensory fiber and then down (i.e., antidromically) a collateral branch supplying an arteriole (fig. 112). See also page 268. Knowledge of these local reactions has obviously wide applicability to the investigation of lesions of the superficial tissues associated with vascular changes, and especially those of an inflammatory nature. They afford another example of the close association between the transmission of pain and vasodilator effects (p. 235).

It may be mentioned incidentally that axon reflexes are not confined to afferent fibers and to vasodilator reactions. The discovery of axon reflexes was made by Langley and Anderson in the investigation of an observation of Sokolowin's, namely, that when the central end of the hypogastric nerve of one side was stimulated, contraction of the opposite half of the bladder occurred. The impulse was shown to have passed centrally for a short distance to an axon branch along which it was transmitted to the inferior mesenteric ganglion of the opposite side from where it was relayed to the vesical muscle. Axon reflexes were later shown by these observers to occur in other parts of the autonomic nervous system (through the ganglia of which no true reflexes occur). The preganglionic fibers of a given spinal segment do not necessarily terminate in the first ganglion of the lateral chain which they enter but pass along the chain for some distance giving off collaterals (axon branches) to cells in the ganglia through which they pass, or they may make no connections until they have

reached a level several segments below that of the segment from which they originated. Therefore, when the sympathetic cord was cut and its central end stimulated, pilomotor and vascular effects were produced in skin areas lying at a higher segmental level than the point of stimulation. That axon reflexes of a more local nature occur in the autonomic plexuses of the intestine and other hollow viscera is generally conceded.

THE BLOOD GASES, LACTIC ACID AND HISTAMINE IN THEIR RELATION TO THE VASCULAR MECHANISMS

CARBON DIOXIDE EXCESS AND OXYGEN LACK. ASPHYXIA

The vasomotor centers are highly sensitive to the gaseous composition of the blood flowing through their vessels.

A high carbon dioxide tension or a low oxygen tension causes an increase in vasoconstrictor tone and a rise in blood pressure. The persistent elevation of the blood pressure which results from a rise in *intracranial pressure* (e.g., cerebral tumor or hemorrhage) is due to compression of the medullary vessels and the interference with the blood supply to the centers; and the marked pressor effect induced by *asphyxia* is the result of the excitation of the vasoconstrictor center by the more venous character of the blood. Three stages in the circulatory effects of asphyxia can be distinguished: (1) For a time after the respiratory muscles of an animal have been paralyzed by curare little change in the level of the blood pressure occurs. (2) In a minute or two the blood pressure, as a result of the arteriolar constriction, commences to mount and may soon reach a value more than double the normal. The vasoconstriction is undoubtedly enhanced by adrenaline liberation, the hormone exerting a direct action upon the vessels. The heart at this time, as a result of the fuller relaxation of the cardiac muscle and the increased venous inflow, beats forcibly; the rate is slowed in consequence of the rise in blood pressure as well as by the action of carbon dioxide upon the cardio-inhibitory center and the tissue of the sino-auricular node. The effect of the carbon dioxide excess upon auriculo-ventricular conduction may result in heart block (p. 190). The capillaries and small veins are dilated and intense cyanosis (p. 375) occurs. (3) The blood pressure falls. This is due to failure of the heart as a result of the anoxemia, and not to the release of the arterioles from the constrictor influence, for, if the volume of the

dney be recorded at this time it will be found that no change occurs before death.

The hypertonicity of the vasoconstrictor center in asphyxia might be due either to the carbon dioxide excess or to oxygen lack. Mathison, however, has studied these two influences separately. When an animal breathed an air mixture containing 10 per cent of carbon dioxide with an equate percentage of oxygen, the arterial blood pressure changed almost immediately, rising within less than a minute to double its previous height; the intestinal volume fell (fig. 113, a). Oxygen lack alone, produced by the inhalation of nitrogen, caused a pressure rise of about the same magnitude; the response was delayed for half a minute or so but was then abrupt (fig. 113, b). Injections of lactic acid or other organic acids into the blood stream produced effects which were in general similar to those of carbon dioxide excess or oxygen deficiency (fig. 113, c). These three factors, carbon dioxide excess, oxygen lack and a rise in hydrogen ion concentration by the injection of lactic acid act upon the vasomotor center and the chemoreceptors of the carotid and aortic areas in a manner analogous to that described for respiratory control (p. 346). Thus, the action of O_2 is exerted mainly upon the center, whereas hypoxemia (or cyanide which suppresses oxidative processes) and acid injections act in a common fashion by raising the H ion concentration of the chemoreceptors.

The spinal centers are also sensitive, though to a less degree, to a rise in hydrogen ion concentration. In the decapitate animal, for instance, under artificial respiration, a rise in blood pressure does not occur until the carbon dioxide percentage of the inspired air has reached 20 per cent, whereas breathing a 5 per cent carbon dioxide mixture may be sufficient to excite the medullary center.

The local effect of carbon dioxide excess or of lactic acid upon the peripheral vessels is one of dilatation. The central and peripheral effects of the hydrogen ion are therefore opposite in direction. During exercise, for example, the acid metabolites formed in the active muscles cause dilatation of their small vessels. On the other hand, any rise in the hydrogen ion concentration of the blood as a whole which may result will, through an action upon the medullary center, cause splanchnic vasoconstriction. Such an effect will contribute to the general rise in blood pressure accompanying exercise (p. 247). The rise in arterial pressure, combined with dilatation

of the vessels within the muscles themselves leads, of course, to a maximum blood flow through the active tissues. It has already been mentioned, however, that unless the exercise is very strenuous no change in blood reaction occurs; and in any event it appears that, as compared with purely

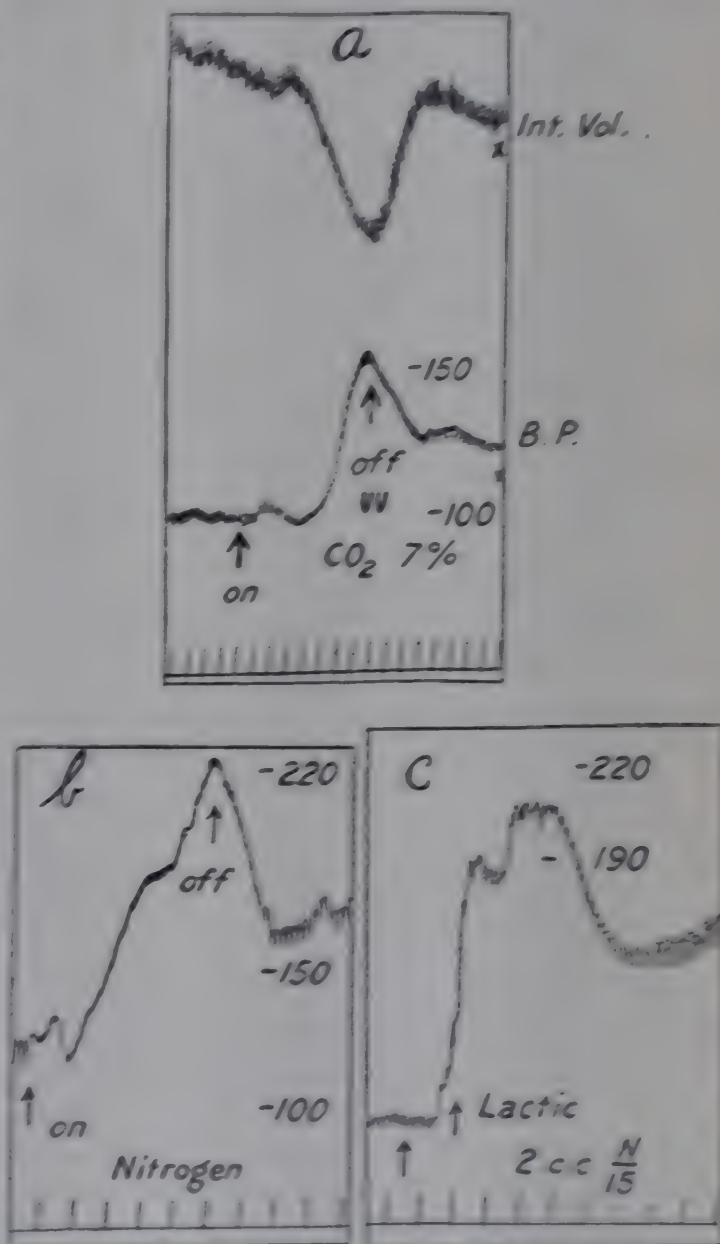

FIG. 113. Showing the pressure effect of carbon dioxide excess, oxygen lack and lactic acid injections. a, tracings of intestinal volume (upper curve) and of blood pressure in an experiment in which a mixture containing 7 per cent CO_2 was breathed. b, shows the rise in blood pressure during the breathing of nitrogen, and c, the rise in arterial pressure resulting from the injection of lactic acid. (After Matheson.)

nervous mechanisms (e.g., irradiation of impulses from cerebral centers), the effect upon the vasomotor center of an increase in hydrogen ion concentration plays a minor rôle in the hypertension of muscular effort. The local vasodilator effect of the hydrogen ion, on the contrary, is of the utmost importance.

The work of Anrep and his associates indicates

that histamine liberation is also a factor in the local vasodilator reaction. These observers found that, whereas the histamine concentration in the venous blood coming from a resting muscle was the same as that in the arterial blood, during contraction of the muscle, the histamine concentration in the venous blood exceeded that of the arterial blood.

CARBON DIOXIDE DEFICIT

Carbon dioxide depletion (acapnia) produces effects upon the vascular system which, in general, are the reverse of those resulting from carbon dioxide excess. The tone of the constrictor center is lowered; arteriolar dilatation results and the blood pressure falls. The *direct* effect of the carbon dioxide lack upon the peripheral vessels is to increase their tone. The capillaries and venules are apparently more responsive to the local action than are the arterioles upon which the central effect predominates.

The effects of carbon dioxide deficit upon the circulation have been studied by Dale and Evans. They found that when cats were over-ventilated at the rate of from 100 to 180 respirations per minute there occurred a rapid and profound fall in blood pressure (to 30 or 40 mm. Hg within a minute or two). In these experiments the depressor effect was due chiefly to the loss of arteriolar tone; the effect of the loss of carbon dioxide or of the respiratory movements (p. 213) upon the action of the heart played an unimportant part. When the excessive ventilation was carried out, using an air mixture containing 5 per cent carbon dioxide, the fall in pressure did not occur, or was observed only at the beginning of the period of hyperventilation. The depressor effects of acapnia were also obtained in decapitated animals, thus indicating that the spinal vasomotor centers are also highly sensitive to carbon dioxide deficit. After destruction of the cord, changes in the tension of the gas caused reverse effects, namely, a rise in pressure with carbon dioxide deficit and a fall with carbon dioxide excess; the direct actions upon the vessels (constriction and dilatation respectively) being then unopposed by the central influence.

In the human subject the effect of forced breathing upon the blood pressure varies. In the majority a fall in pressure results but in some the pressure remains unchanged; in a few it rises. The depressor effect when it occurs is not due altogether to the effect of carbon dioxide deficit upon the vasomotor center but is largely

the result of the mechanical effect of the forcible expiratory movements (p. 213) which impede the venous return to the heart (Vincent and Thompson). This is evidenced by the fact that in many persons the depressor effect can still be produced when the forced breathing is carried out with air containing a high percentage of carbon dioxide. In those persons in whom the pressure does not fall, its failure to do so may be due to the irradiation of impulses from the motor area to the vasomotor center which enhances the latter's tone, or to the compensatory vasoconstriction resulting from the local effect of the carbon dioxide deficit. Vasoconstriction of the cutaneous vessels is often clearly evident from the pallor which occurs in the period of apnea following forced breathing; the cutaneous circulation is sometimes slowed to such a degree that cyanosis appears. Stewart by means of his calorimetric method, has also demonstrated under such circumstances the slowing of the blood flow through the hands. Furthermore, if the vessels are kept maximally dilated by means of a hot bath, in a subject who ordinarily either shows no blood pressure effect as a result of forced breathing or gives a pressor response, then acapnia causes a depressor effect. The antagonism between the central and local effects of carbon dioxide upon the vessels can also be demonstrated by applying a tourniquet to the arm. Forced breathing then causes a much less marked effect upon the vessels of the asphyxiated arm (owing to the high carbon dioxide tension in the blood of the obstructed vessels) than upon those of the opposite arm.

Traube-Hering waves

These are slow, rhythmical waves which appear on the blood pressure tracing of an animal poisoned by curare, absinthe, morphine and certain other drugs. They also appear in asphyxia or in any condition in which the oxygen in the blood supplying the medulla is markedly reduced or the carbon dioxide content increased. They may therefore appear in hemorrhage or when (as a result of raised intracranial pressure) the circulation through the medulla is interfered with. The frequency of the waves is from 5 to 10 per minute. They are due, apparently, to periodic variations in tone of the vasomotor center and should not be confused with those of splenic origin (p. 54).

THE CONTROL OF THE VEINS

The veins receive constrictor fibers from the sympathetic. The innervation is not confined to the minute veins, but includes the larger superficial veins of the limbs, intestines, spleen, liver and kidney. There is no evidence, however, that the venae cavae or the veins of the muscles are furnished with constrictor nerves. Like the arteries, veins exhibit constrictor tone, dilating when their nerves are sectioned. The vein wall responds readily by constriction to direct mechan-

cal stimulation, e.g., puncture by a needle. Certain superficial veins receive dilator impulses (antidromic) via sensory fibers. Dilatation of the inferior mesenteric vein has also been observed following stimulation of the posterior nerve roots of the lower thoracic segments. In emotional states constriction of the superficial veins has been observed and reflex changes in caliber, analogous to those occurring in the arterioles, result from various types of peripheral stimulation. According to Heymans the veins take part in the pressor or depressor reflex induced from the carotid sinus.

Carbon dioxide acting locally upon the venous walls exerts a dilator effect; reduction in carbon dioxide tension increases venous tone. Yandell Henderson and associates attach a great deal of importance to the tonic influence exerted upon the venous mechanism by carbon dioxide. They claim that acapnia produces constriction of the peripheral veins and so interferes with the return of blood to the heart (p. 213). The rise in venous pressure which results from breathing an air mixture rich in carbon dioxide they ascribe to relaxation of the smaller veins and the increased flow of blood from the arterial side.

The reactions of the veins to adrenaline, pituitrin and several drugs are similar to those of the arterioles to such agents.

MEANS EMPLOYED TO DEMONSTRATE THE PRESENCE OF VASOCONSTRICTOR OR VASODILATOR FIBERS IN A PERIPHERAL NERVE TRUNK

If both types of vasomotor fibers exist in a given nerve the constrictor effects predominate when the nerve trunk is stimulated and may obscure entirely any coincident excitation of dilator fibers that may occur. In order, therefore, to demonstrate the presence of the latter it is necessary to remove the constrictor influence before stimulating the mixed nerve. This may be accomplished by sectioning the nerve and allowing time for *degeneration of the vasoconstrictors* to occur, which is some time (2 to 3 days) in advance of the degeneration of the dilators. At the end of this time, therefore, pure vasodilator effects are obtained. The two types of fibers also respond more readily to *different kinds of stimuli*, and this fact may sometimes be employed to detect the presence of vasodilator. The vasoconstrictors respond more readily to strong electric shocks of high frequency, the dilators to comparatively weak and slow rhythmic shocks. The

latter also respond more readily to mechanical stimulation. *Ergotoxine* is a drug which acts in a selective manner, as shown by Dale, by abolishing motor effects of the sympathetic nervous system. The vasoconstrictors are paralyzed but the vasodilators are unaffected. Therefore when a nerve, such as the splanchnic, which contains both types of fibers is stimulated after administration of this drug, the response is one of pure vasodilatation.

Several methods are available for the demonstration of the actual vasoconstrictor or vasodilator effect. (1) *Inspection* of the organ or vascular region supplied by the nerve under investigation. Flushing or blanching indicates vasodilatation or vasoconstriction respectively. The method is particularly suitable to superficial and transparent structures, such as the frog's web or the ear of the rabbit; the latter was employed by Claude Bernard when he discovered the vasomotor nerves.

(2) *Change in temperature* of a superficial part supplied by the stimulated nerve. The blood in the deeper tissues is considerably warmer than that flowing through superficial vessels. When the arterioles dilate the part becomes flushed with blood drawn from deeper regions, i.e., the cutaneous blood flow is increased; the temperature rises in consequence. A reverse effect upon the superficial temperature is caused by vasoconstriction. The temperature changes may be detected by means of a sensitive thermometer held in contact with the surface or, more precisely, by a thermo-electric couple inserted into the tissue, e.g., the skin, mucous membrane, etc.

(3) *Plethysmographic method*. The principles of this method have been explained elsewhere (p. 149). It is applicable to the demonstration of vascular changes in such organs as the kidney, the intestine or a limb, which can be isolated from surrounding parts. The instrument registers changes in volume and these, when they follow stimulation of the nerve supplying the region, are taken to indicate corresponding changes in the caliber of the vessels. Both artery and vein leading to and from the organ must be equally free from compression, since interference with the flow through one or other vessel will cause alterations in volume of the part. When a limb is under investigation it is usually desirable to eliminate muscular movement by the administration of curare. It is essential that changes in volume resulting from passive distensions or collapse of the vessels by changes in the general

arterial blood pressure be distinguished from active vasodilatation and vasoconstriction, respectively. That is, a rise in the arterial blood pressure may cause greater filling of the vessels in a purely passive manner and swelling of the organ in consequence—a mere distension of the vascular

FIG. 114. Upper figure shows simultaneous tracings of carotid blood pressure and volume of kidney. Between X and X the peripheral end of the divided tenth dorsal nerve was stimulated. Time-marking = seconds. (After Bradford.) Lower figure shows the effect upon the kidney volume (Pl.) and arterial pressure (B.P.) of stimulating the central end of the vagus T, time-marker; S. stimulus. (After Bayliss.)

bed. On the other hand, a fall in general blood pressure may drain blood from the organ and cause its volume to shrink. For these reasons a blood pressure tracing must always accompany the plethysmographic records. Only when the blood pressure tracing remains unchanged or the two tracings take opposite directions, i.e., a rise in arterial pressure accompanied by a fall in volume or a fall in pressure coinciding with a rise in volume, can a definite conclusion regarding the change in the caliber of the vessels be drawn (fig. 114)

(4) *Outflow from veins.* In a small organ, such as the salivary gland, changes in the blood flow through it may be detected by noting the rate of flow and color of the blood issuing from the veins. Usually the smaller veins are tied off and the blood as it issues from one or two larger veins collected in a graduated receptacle.

The *thermo-stromuhr* (p. 145 and p. 277) may also be employed to determine variations in the volume flow through the organ, the measurement being made either of the ingoing or outgoing blood.

Vasodilator substances. The results of experimental work in the last few years have added several new names to the list of vasodilator substances which may be extracted from the tissues.

Acetylcholine. More is known about the physiological significance of this choline ester than of any of the other vasodilator substances. Its formula is:

Acetylcholine, as discussed elsewhere (p. 946), is liberated from parasympathetic postganglionic nerve endings and from the preganglionic endings of both parasympathetic and thoracic autonomic fibers. *Choline* itself, which has the following formula

and as a constituent of lecithin and sphingomyelin (p. 595), has an extremely wide distribution in the body, is a well-known vasodilator. Its activity is of a low order in comparison with acetylcholine, the vasodilator effect of choline being increased by at least one thousand times after acetylation. There appears to be very little free choline in the body, and the amount of acetylcholine, rather than choline, appears to vary under physiological conditions. Choline acts in the same manner as acetylcholine on the blood vessels. Its action on liver fat has been discussed elsewhere (p. 602).

Histamine:

Histamine is also very widely distributed in the body. It can be readily formed *in vitro* by the action of bacteria of the colon typhoid group upon the amino-acid histidine. This mechanism probably accounts for the formation of histamine in the intestine. The method by which histamine is formed in tissues has not been established. Small amounts are present in muscle, while the lung in herbivora and the liver and intestinal tract in omnivora may contain relatively large amounts. The concentration of histamine in human blood is from 1 to 8 micrograms per 100 cc. This is contained mainly in the white cells and most probably in the eosinophils (Code). A substance indistinguishable from histamine is apparently responsible for the first part of the triple response in skin (p. 268) but chemical identification has not been made. "Gastrin" and histamine (p. 434) are indistinguishable. The subcutaneous injection of one-quarter to one-half milligram of histamine produces a copious flow of acid gastric juice in man (p. 442). The mechanism of action of histamine on the blood vessels varies with the species studied, but in man both arterioles and capillaries are dilated. The intravenous administration of a ten-thousandth of a milligram causes an appreciable fall of blood pressure in the etherized cat. One-thousandth of a milligram given intravenously produces a sharp fall of blood pressure in unanesthetized man. The unanesthetized organism is not so susceptible to histamine as the anesthetized. While Abel's researches indicated the wide distribution of histamine in biological material the base was first prepared in crystalline form from perfectly fresh tissue by Best, Dale, Dudley and Thorpe. The possibility that histamine may possess physiological significance has been materially increased by the finding that it is liberated in anaphylactic shock from the liver in the case of the dog and from the lung in the guinea-pig. Histamine may not be the only substance liberated in this condition but it accounts for most of the signs of anaphylaxis. It is important also, as Kalk has shown, that irritation of the skin in certain susceptible people (dermographism) produces a definite secretion of acid gastric juice quite comparable to that which the subcutaneous injection of histamine might evoke. Histamine is destroyed by an enzyme system, histaminase (Best and McHenry) which is found in various tissues, but particularly the kidney and small intestine. The physiological significance of this enzyme has not been established.

Adenosine and derivatives:

In 1929 Drury and Szent-Györgyi showed that the active constituent of certain extracts from skeletal and cardiac muscle which produced a characteristic condition of heart block in the guinea-pig was adenosine. This substance was also shown to have a peripheral vasodilator effect, which has been found to be exerted mainly, if not entirely, upon the arterioles. The heart block (p. 190) produced by adenosine is relieved by barium. Adenosine administered subcutaneously causes a migration of leucocytes to the site of injection, an effect which is not produced by histamine. Histamine and adenosine may both be concerned in inflammatory reactions and in the effects upon the circulation produced by extensive tissue damage. Their exact significance in this connection awaits further investigation. Adenosine and adenylic acid are relatively inert vasodilators with a potency of somewhat the same order as choline. They may be present, however, in considerable amounts in certain tissues.

Kallikrein. Kallikrein is the name given by Frey and Kraut to a vasodilator substance obtained from normal urine. This substance has not yet been obtained in pure form, but it probably differs from all other vasodilators. It does not cause constriction of the bronchioles in the guinea-pig, as histamine does; it lowers the blood pressure of the rabbit, while histamine does not do so when the ordinary anesthetics are used. This substance is rapidly destroyed by blood serum, but the activity is recovered when acid is added. It is suggested that kallikrein is liberated when the tissues become acid through metabolic activity. This would, of course, produce vasodilatation and increased blood flow. The site of formation of kallikrein is not known, although pancreatic tissue has been used for its preparation.

Identification of vasodilator substances. In addition to these substances there are undoubtedly others which cannot be exactly characterized as yet. The vasodilators we have mentioned may be identified by the following means. Kallikrein and adenosine and its derivatives are destroyed by acid hydrolysis; choline and histamine are resistant to this procedure. Acetylcholine is very susceptible to alkali and may be completely destroyed in a short time in a solution at pH 8 to 9. Atropine antagonizes the action of choline or of acetylcholine but exerts no effect upon the action of histamine. Positive evidence for the presence of

adenosine is its characteristic effect upon the guinea-pig's heart. Kallikrein will produce a fall in blood pressure in the atropinized rabbit, which neither choline nor acetylcholine will do, while it exerts no effect on the guinea-pig's heart. These vasodilators may also be separated by the use of precipitating agents and by other chemical procedures.

VASOCONSTRICTOR SUBSTANCES. Among the best known vasoconstrictor agents are *pituiridin* and *adrenaline* (p. 686) and compounds chemically related to the latter, e.g., *ephedrine*, *tyramine* and *benzedrine*. *Barium chloride* is also a powerful vasoconstrictor. *Tobacco smoking* is generally stated to cause peripheral vasoconstriction, the effect being usually not demonstrable unless the smoke is inhaled. The experiments of Bolton, and associates and of Mulinos and Shulman throw doubt upon the conclusion that the vascular effect is due to the absorption of some constituent of the inhaled smoke. They found that a deep inspiration of pure air causes a marked reflex constriction of the cutaneous vessels of the forearm and hand. The phenomenon is enhanced by an irritant or painful stimulus, e.g., inhalation of smelling salts, pinching the skin, etc., and is more pronounced if the respiratory movement is mainly thoracic. Helmer and his associates have shown that the vasoconstrictor agent found in the urine of smokers is nicotine, which they have isolated in crystalline form as a picrate. *Sodium nitrite* contrary to the general belief, causes, as shown by Weiss and his associates, arteriolar constriction. The fall in blood pressure which follows the administration of an appropriate dose, and which may result in collapse and syncope when the subject stands is due to the reduction in venous tone and, as a consequence, the pooling of blood in peripheral veins. The effects produced by nitrite, namely, the fall in blood pressure, slowed peripheral blood flow, acceleration of the heart and fall in venous pressure, are identical, according to Weiss with the peripheral circulatory collapse seen clinically (e.g. in pneumonia and other infection, and in surgical shock).

PERIPHERAL VASCULAR DISEASE

RAYNAUD'S DISEASE

In this condition, which was first described by Raynaud in 1862, the fingers, sometimes the toes or rarely the ears and nose, are the seat of periodic attacks of vascular spasm. The attack lasts as a rule for a few minutes, but may persist for an hour or two. The spasm is usually induced by exposure to cold and frequently appears in symmetrical parts on the two sides of the body. The affected members become cyanosed and cold, later intensely pale and numb (dead fingers). The color change commences in the finger tips and spreads toward the bases of the fingers. As the attack passes off the part again becomes cyanotic, then red and hot; the numbness is re-

placed by burning pain. According to Lewis the spasm involves the digital arteries. The pulse at the wrist or ankle persists during the attack. The local asphyxia may lead to ulcers, scleroderma, rarefaction of the terminal phalanges, and other trophic changes. Gangrene, it is said, sometimes results; it is likely, however, that when this occurs the vascular condition should not have been classed as a true example of Raynaud's disease, but that the vessels had been the seat of structural changes which obliterated their lumina rather than of a simple spasm.

The disease, since Raynaud's first description of it, has been generally attributed to hyperactivity of the vasomotor (vasoconstrictor) nerves. Sympathetic ganglionectomy is, therefore, frequently resorted to in an effort to abolish the attacks. Lewis has shown, however, that a typical attack may be induced in a subject upon whom this operation has been performed, by exposing the affected part to cold (as by immersing it in cold water). He concludes therefore that the fault lies not in the nervous control but in the vascular wall itself. The following observations cited by Lewis substantiate his view.

(1) If one finger of a subject of the disease be immersed in cold water, an attack confined to this finger may be induced. Such a localized result cannot be explained upon the basis of a nervous reflex.

(2) Anesthetization of the ulnar nerve of a normal person by means of novocaine causes dilatation of the vessels of the little finger (removal of vasoconstrictor tone). The vascular spasm in Raynaud's disease cannot be released in this way.

(3) If a subject suffering from Raynaud's disease affecting both hands, and upon whom a unilateral ganglionectomy had been performed, be seated in a cool room with both hands placed in cold water, the vascular spasm which results is more pronounced on the non-sympathectomized side. If, however, the rest of the body is warmed while the hands are immersed in cold water, the attack is more pronounced on the sympathectomized side. In the first experiment the greater degree of spasm on the non-operated side is attributed to the added effect of a vasoconstrictor reflex. The greater degree of spasm on the operated side in the second experiment is attributed to the absence of dilator sympathetic fibers. Though a nervous influence is evident in these observations the essentially local nature of the fault is also indicated.

Ganglionectomy, even though it does not remove the fundamental cause of the condition, does, nevertheless, exert a decidedly beneficial effect. The attacks are less frequent and intense after the operation; normal vasoconstrictor tone and,

as just indicated, the reflex responses to cold having been abolished, a more intense reaction of the arterial wall itself must occur before arrest of the circulation to the part can result.

Simpson, Brown and Adson on the other hand, do not consider that Raynaud's disease is due primarily to a fault of the vascular tissue. These observers maintain that only in the advanced stages of the disease is the vascular wall itself abnormal and that in milder cases the fault is essentially vasomotor in character. They point out that Lewis' crucial experiments were performed upon severe or complicated cases of the disease.

ERYTHROMELALGIA

Erythromelalgia is a rare but interesting condition characterized by attacks of painful redness of one or both feet, or occasionally of the hands. The pain is burning in character and is induced by warming or exercising the part; or by allowing it to hang down. Rest, elevation of the part or the application of cold tends to relieve the pain. Erythromelalgia has been attributed to vasodilation resulting from some abnormality of the vascular nerves. Lewis finds, however, that the essential abnormality in these cases is not vasodilatation, for, an equivalent degree of vasodilatation may occur in normal subjects in response to warmth or exercise yet pain does not result. Erythromelalgia, or *erythralgia* as Lewis prefers to call the condition, is not of vasomotor origin. The abnormality in these cases is apparently a hypersensitive state of the cutaneous pain fibers to heat or tension. This "susceptible state" of the skin in erythralgia is altogether analogous to that seen in inflammation, and to that which can be induced in any normal person by certain types of cutaneous injury—exposure to ultra-violet light, repeated rubbing or stretching, burns, etc. It is well known that the pain endings of skin injured in these ways are very sensitive to warmth or to tension. Warming the part either by increasing the blood flow through its vessels, or by the application of heat causes burning pain. Pain also results when the part is dependent, the engorged vessels then causing tension upon the hypersensitive nerve endings.

Lewis suggests that in the pain associated with erythralgia and with the types of cutaneous injury just mentioned a chemical substance liberated in the skin serves as the immediate stimulus to the nerve endings. The observation that the pain which follows repeated rubbing or stretching of the normal or of the erythralgic skin is prolonged and intensified by arresting the circulation to the part, supports this conception (p. 270).

ACROCYANOSIS

In this disorder the hands and less commonly the feet are persistently cold, blue and sweaty. Exposure

to cold intensifies the cyanotic color. In the case of the hands the cyanosis commences at about the level of the wrist and deepens as it is traced toward the fingers. There is puffiness of the fingers but trophic disturbances are unusual. The milder forms of the disorder are closely allied, according to Lewis, to chilblains. The disorder is due to increased tone of the cutaneous *arterioles* resulting from hypersensitivity to cold. The condition has not a nervous basis; the fault is in the vascular wall itself, the cyanosis persisting unchanged after anesthetizing the ulnar nerve with novocaine. We have seen that in Raynaud's disease the spasm is of the digital *arteries*. In acrocyanosis the cutaneous circulation is slowed as a result of arteriolar constriction; the partial asphyxia causes capillary dilatation and an increase in the quantity of blood in the skin. The

FIG. 115. Warm chamber with subject in position for observing effects in the hands. The neck and forearms pass through canvas sleeves terminating in purse strings. The chamber is divided into two parts at the dotted line. For use with the lower extremities the front wall is made with simple upright front with two appropriately cut outlets for the thighs. (After Lewis and Pickering.)

slower blood flow, by allowing the hemoglobin to give up a greater part of its oxygen store, is responsible for the blue tint of the skin; the depth or intensity of the color is due to the fullness of the vessels (p. 267).

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

This is an *organic* vascular disease involving the arteries (and to a less extent the veins) of the extremities. The condition in the majority of cases is confined to the lower limbs. The vessels are stiffened and hard. The adventitia is thickened; the media shows atrophy of its muscle and an increase in connective tissue; and, active proliferation of the intima occurs, several layers

of cells being formed. The marked narrowing of the vascular lumen which results is followed by thrombosis. This and not the intimal proliferation itself is responsible for the final obliteration of the vessel. Organization of the thrombus, i.e., its invasion by fibroblasts and its conversion into fibrous tissue, follows. Some restoration of the circulation through the vessel may occur later as a result of the formation of new channels within the substance of the organized thrombus; but whether or not this does follow the blood supply to the part is greatly reduced.

Among some of the earlier manifestations of the condition are: fatigue of the limbs upon erection; intermittent claudication; hypersensitivity of the vasoconstrictor reactions of the extremities to cold resulting in attacks of pallor or cyanosis, coldness and numbness or a dull ache. A definite reduction in blood flow through the part may be demonstrated by the calorimetric method of Stewart (p. 149). Extreme variations in the color of the limb result from altering its position in relation to the level of the heart; when the affected member is dependent undue redness or cyanosis results, whereas when raised above heart level it becomes intensely pale and waxy in appearance.

As the pathological changes progress the pulse disappears from the wrist or ankle, or even from the popliteal or brachial artery; ulcers and other trophic disorders appear and ultimately gangrene of the toes or fingers sets in, requiring amputation. The vascular obliteration tends, however, to creep upwards necessitating amputation at successively higher levels.

The cause of the disease is unknown; some believe it to be of infective origin. Excessive use of tobacco is strongly suspected of being a predisposing factor. Buerger and others have remarked upon the very high incidence of the condition in the Jewish race; of a series of 150 cases reported by Brown and Allen from the Mayo Clinic over 50 per cent were Hebrews. The disease occurs almost exclusively in males, whereas Raynaud's disease with which it is likely to be confused, especially in its early stages, affects females predominantly. Another feature distinguishing it from Raynaud's disease is that in the latter, the color of the skin is affected little or not at all by elevation of the limb; and the pulse in the larger arteries does not disappear. It is possible that spasm of the vessels as a result of hyperactivity of the vasomotor nerves is the initial abnormality in thromboangiitis obliterans. The constriction of the vasa vasorum, it is conceived, may, by

interfering with the nutrition of the arterial wall initiate the characteristic structural changes.

It is, of course, only during the earlier stages of the condition, i.e., when spasm due to increased vasoconstrictor reactivity is a contributing factor and before organic changes have progressed to the point where they have occluded the vessels that treatment of any sort can be expected to bring about any real benefit. When a spastic factor can be demonstrated sympathectomy frequently results in very notable improvement. Even when the larger arterial vessels are obliterated sympathectomy, by removing the vasoconstrictor tone of collateral vessels, may be followed by a definite improvement in the blood supply to the part.

There are several methods to choose from for the detection of vascular spasm. The temperature of the part may be taken by means of a skin thermometer or a thermocouple before and after one or other of the following procedures, which, normally, cause vasodilatation and raise the temperature of the part. (a) Heating the entire body, with the exception of the head and the affected part itself, in a cabinet (fig. 115). (b) The induction of fever by the injection of a foreign protein, typhoid vaccine. (c) Spinal anesthesia which temporarily paralyzes the vasoconstrictors. (d) Anesthetization of a peripheral nerve. (e) The intravenous injection of hypertonic saline by increasing the blood volume will tend to cause a compensatory vasodilatation. A rise in temperature of the part, following one of these procedures, indicates the previous existence of a spastic element. The greater the degree of spasm the more pronounced and rapid is the temperature rise. If the occlusion is entirely organic in nature no change in temperature results.

Instead of recording the skin temperature the blood flow through the affected part may be estimated by the calorimetric method before and after one of the procedures just enumerated.

Cervical rib may cause changes in the circulation of the upper extremity not unlike those due to thromboangiitis obliterans. The subclavian artery tends to be compressed between the bone and the scalenus anticus muscle with consequent reduction in the volume of the pulse of the affected side. But the peripheral vascular disturbances are due mainly, according to the view of Stopford and Telford, to the pressure of the supernumerary rib upon the vasoconstrictor fibers in the lowest trunk of the brachial plexus. Sensory and motor phenomena as a result of pressure upon the somatic fibers also sometimes occur. Constriction of the vasa vasorum with consequent interference with the blood supply of the vascular wall has been suggested as re-

sponsible for the structural changes which ultimately lead to thrombosis and occlusion of the arterial lumina. Lewis, however, dissents from this view. "Why," he asks, "if pressure upon nerve fibers is the cause of the vascular condition, are the effects always of an irritative nature (vasoconstriction)?" "Why do not paralytic manifestations (removal of vasomotor tone with consequent vasodilation) appear at some later stage?" He suggests that the blocking of the peripheral vessels is of embolic origin due to pressure injury of the subclavian artery, and the formation upon its wall of thrombi which are whisked away in the blood stream from time to time.

INTERMITTENT CLAUDICATION

(*claudicare*, to limp)

This is a condition (described by Charcot in 1856) in which, as a result of organic narrowing of the arteries of a limb and consequent restriction of its blood supply, severe pain is experienced in the muscles during exercise. The pain has been attributed to a muscular cramp or to spasm of the vessels. Neither of these explanations can be entertained, for the muscles are flaccid during the attack; the abnormal stiffness of the arteries seems to preclude the possibility of their being narrowed appreciably by spasm; and the smaller vessels are in all likelihood dilated rather than constricted during the attack.

The essential cause of intermittent claudication is a relative anoxia of the muscles—they are called upon to perform work for which the oxygen supply is inadequate. Lewis has shown that pain identical in character with that occurring in this condition can be induced by exercising any normal limb during the arrest of its circulation. When the circulation is restored, an immediate increase in the volume of the limb occurs which is taken to indicate that the vessels were dilated during the pain. In a patient suffering from the disease in one limb it was shown that the pain occurring in the limb during exercise was practically the same with regard to its time of onset, development and duration as that induced by exercising the sound limb during circulatory arrest.

The fundamental importance of anoxia in the production of the pain is also evident from the observations of Pickering and Wayne who found that exercising the muscles of an anemic subject, in whom there was no evidence of arterial disease, caused the characteristic pain of intermittent claudication. Kissin also showed that exercise performed by normal persons during anoxia

(induced by breathing an air mixture containing a low percentage of oxygen) caused the typical cramp-like pain. The clinical experiments of Lewis indicate that the direct cause of the pain is not oxygen lack itself but the stimulation of sensory nerves by the metabolic products of muscular activity. Ordinarily these are removed by oxidation, but they accumulate when the blood supply is inadequate. He refers to the pain stimulus as "factor P." The evidence supporting this conception is as follows:

(1) The pain does not vary with the individual contractions but is a steady ache.

(2) Using a standard test (maximal grip exerted by by thumb and index finger, recorded isometrically, and repeated at the rate of one per second) it was found that in normal subjects with the circulation to the arm arrested, the pain commenced in about 35 seconds after the commencement of the exercise and took another 53 seconds to reach the point where it became intolerable. The pain disappears within 3 seconds after restoring the circulation—presumably as a result of the removal of "factor P." If, on the other hand, occlusion of the vessels is maintained, the pain persists.

(3) Lewis found that the time of onset of the pain is determined by the total amount of work performed rather than by the length of the exercise period. Thus, when the circulation of a normal limb is arrested, pain ensues after the same number of contractions of equal strength whether they are repeated in rapid or in slow succession. On the other hand, if a constant rate is maintained the pain follows sooner with strong than with weak contractions. If, however, the circulation to the part is only partially obstructed (Katz, Lindner and Landt) or if air containing a low percentage of oxygen is breathed (Kissin), the amount of work necessary to cause pain is lessened by increasing the rate at which the contractions are repeated—the chemical factor presumably accumulating more rapidly as a result of the shorter time intervals allowed for its removal.

(4) If, after the pain has been relieved by restoring the circulation to the part, the vessels are again occluded and the limb exercised, the time of onset of the pain ensues earlier, the shorter the period during which the blood had been permitted to flow. This result suggests that products accumulated during the previous exercise period, if not given sufficient time to be removed, are carried over to the second period; the concentration necessary for stimulation is, therefore, reached sooner.

The nature of the chemical pain factor is unknown; Katz and associates believe it to be acid in character and non-volatile. The ingestion of sodium bicarbonate was found to increase the amount of exercise required to cause pain.

The pain in angina pectoris is generally believed

to be produced through a mechanism essentially the same as that causing pain in intermittent claudication.

WOUND SHOCK—CLINICAL AND PHYSIOLOGICAL CONSIDERATIONS

That state of collapse which follows two, three or four hours after a severe tissue injury is variously spoken of as *wound, traumatic, surgical* or *secondary* shock. It is a condition quite distinct from the so-called *primary shock* which supervenes immediately after an injury. Primary shock has a nervous basis; pain and psychic factors, through their effect upon the vascular system, play a prominent rôle.

Secondary, or surgical shock is characterized by a profound fall in blood pressure; pallor and coldness of the skin; cyanosis of the finger tips and lobes of the ears; sweating; fall in body temperature and of the metabolic rate; rapid shallow breathing; small, rapid pulse; apathy: and other manifestations of collapse. Further investigation of a patient or animal in shock will usually reveal marked reduction in the circulating blood volume, even though no hemorrhage has occurred. In very severe cases the systolic blood pressure may be no more than 60 mm. Hg. There is a rise in non-protein nitrogen of the blood, and a fall in the alkali reserve.

When the chest of an animal in deep shock is opened the heart is found to be beating vigorously. The cause of the low blood pressure is, therefore, not of cardiac origin. The heart cavities, however, are incompletely filled. The great veins are depleted of blood, the venous pressure is low, the cardiac output reduced and the circulation through the peripheral vessels slowed.

Slowing of the peripheral blood flow and reduction in the cardiac output occur early in shock and precede the fall in blood pressure.

There is constriction of the arterioles of the splanchnic and cutaneous areas. This is probably a compensatory reaction—a response of pressor mechanisms (e.g., sinus and aortic nerves, p. 240, 241) to the underfilled state of the vascular system.

Inasmuch as many observers have reported an increase in the corpuscular concentration of the blood, or *hemoconcentration* as this has come to be called, it has been the general belief that an essential and fundamental feature of secondary shock is the leakage of plasma from the capillaries as a result of an undue permeability of their walls. But the loss of plasma through excessively permeable vessels remote from the injured region has

yet to be proved. In animal investigations into secondary shock (as produced by mechanical trauma) hemoconcentration to a degree which would indicate any great reduction in blood volume due to plasma loss is by no means a general finding. Furthermore, no direct evidence of plasma loss into the tissues generally has been secured, and even when hemoconcentration exists there is some indication that plasma is removed from the general circulation by becoming "locked up" or pocketed in the minute peripheral vessels rather than by leakage from the vascular system.

Widespread capillary dilatation is a factor which has been generally thought to be present in and largely responsible for the shock state. A considerable body of evidence can be cited in support of this belief. Morrison and Hooker observed an increase in the volume of an intestinal loop when shock supervened, and Mann found that, whereas about 24 per cent of the blood volume of a normal animal is held in peripheral vascular areas and the remaining 76 per cent in the heart and larger vessels, in shock (produced by exposure and handling of the abdominal viscera) 61 per cent was contained in the peripheral vessels.

Pooling of blood in peripheral vascular areas could quite conceivably account for the main features of shock. Any great enlargement of the capillary bed would alone cause a fall in blood pressure without any loss of blood from the vascular system. The maintenance of the normal arterial blood pressure (p. 121) depends upon a nice adjustment of the capacity of the vascular system to the volume of blood. Variation in either factor would have practically the same effect upon the blood pressure.

Moreover, a reduction in the effective or circulating blood volume would be expected to result from any great dilatation of capillary areas. Pooling of blood at the periphery of the vascular system would, by reducing the venous return, deprive the heart of an adequate volume of blood to maintain the blood pressure at its normal level. It may be mentioned in support of this conception that Erlanger has described the packing of corpuscles in the dilated capillaries of the intestinal villi in shock. In the shocked patient, also, slowing of the peripheral circulation is evident from the unusually slow return of color to the skin after blanching, as by the slight pressure of one's finger. It should be pointed out that determination of the blood volume by indirect methods fails to distinguish between a reduction

of blood volume due to actual loss from the vascular system and a reduction of circulating blood volume. In other words, blood which has become sequestered in vascular areas out of general circulation is not included in blood volume estimations by the usual methods.

THEORIES CONCERNING THE PRIMARY CAUSE OF WOUND SHOCK

Many theories have been advanced in attempts to explain the genesis of the shock state. Among those which have found favor from time to time with different groups of workers are the following: exhaustion or paralysis of the vasomotor center as a result of its bombardment by sensory impulses from the traumatized tissues (Crile); "blowing off" of carbon dioxide (acapnia) due to stimulation of the respiratory center by afferent impulses arising in the injured part, or during the hyperpnea of the early stages of general anesthesia (Y. Henderson); multiple pulmonary emboli caused by the liberation of fat globules from damaged bone and subcutaneous tissues (Porter); adrenal exhaustion; etc. None of these theories has stood the test of critical investigation. There is no evidence that the activity of the vasomotor center is depressed in shock. It has been mentioned that arteriolar constriction rather than dilatation occurs, and Porter found that the vasomotor reflexes, both pressor and depressor, were unimpaired in the shocked animal. Nor is acapnia or alkalosis present in traumatic shock. Acidosis is more likely to appear, though not in a causative rôle, the reduced circulation rate and consequent anoxia of the tissues resulting in the accumulation of fixed acids. Porter's fat embolism theory has not been substantiated. Swingle and his associates have directed attention to the very close similarity between the effects of adrenal (cortical) excision and the shock state (p. 694). Low blood pressure due to plasma loss, and collapse are prominent features following suprarenalectomy. The effects of this operation are, however, much slower in onset (several days) and there is no direct evidence that deficiency of the hormone of the adrenal cortex is a factor in the causation of traumatic shock. Moreover cortin is of very uncertain benefit in traumatic shock. With regard to the adrenal medulla, in Cannon's view this part of the gland is more likely to be overactive than deficient in shock (p. 261).

The foregoing theories are given mainly for their historical interest. Today, opinion is divided between two schools. (a) One of these believes that a toxic agent formed in the injured tissues is carried in the blood stream and exerts a widespread effect upon the vascular system. This is the *toxemic theory* of shock. (b) The other school holds that the loss of circulating fluid into the

damaged parts is the major factor. This will be referred to as the *theory of local fluid loss*.

The toxemic theory of shock

As a result of the investigations of a number of workers into the shock state, as seen in wounded soldiers in the war of 1914-1918 or as produced experimentally in animals, the theory arose that the main features were due to the action of a depressor substance formed through the destruction of tissue, especially of muscle. A few years before the last war Dale and Laidlaw had reported upon the action of *histamine*. Struck by the resemblance of the effects of this amine to certain features of traumatic shock, Dale, Laidlaw and Richards in 1919 re-investigated its actions. When injected into animals in doses of 1 mg. per kilogram of body weight, histamine exerts a profound depressor effect upon the circulation, namely, a fall in blood pressure, due to peripheral vascular dilatation. Increased capillary permeability with consequent transudation of plasma from the vessels is also a well recognized action of histamine (p. 269). The fall in blood pressure is, of course, the outstanding feature of shock. Vasodilatation and increased capillary permeability leading to reduced plasma volume were (upon the assumption that the blood pressure fall was due to histamine or a histamine-like substance) supposed to exist as well. The reports of hemoconcentration and a reduction in blood volume in shock seemed to confirm these suppositions. Certain clinical observations were also in accord with a toxemic theory; a tourniquet applied to a damaged limb, for example, appeared to postpone the development of shock, presumably because a toxic substance was prevented from entering the general circulation. It was also generally conceded that amputation of a contused and lacerated part favored recovery from shock, arrested its further development or tended to prevent its onset. Moreover, injury to muscle, which it was presumed was relatively rich in vasodilator substances such as histamine, was especially likely to be followed by shock.

Thus, the toxemic theory of shock in which a histamine-like substance, or histamine itself, was the responsible agent seemed well authenticated and seemed to be finally established by the experiments of Cannon and Bayliss. These observers crushed the limbs of animals and reported that a fall in blood pressure did not result so long as the vessels of the injured part were occluded, though the nerve trunks remained intact. Upon restoring

the circulation a fall in blood pressure occurred. Division of the nerves, on the other hand, without arrest of the circulation in the limb did not prevent the onset of shock.

Others who have repeated Cannon and Bayliss' experiment have not been able to obtain the same results; some indeed have reported findings quite the reverse. Simonart, for example, traumatized a hind limb after occlusion of the vessels, and section of the sciatic and femoral nerves. Shock did not occur when the vessels were released. If, however, the innervation of the limb remained intact, shock ensued even though the circulation had been arrested. Nor has any worker been able to demonstrate the presence of a substance in the venous blood coming from a traumatized limb which would, when injected into a normal animal, induce the shock state. Parsons and Phemister found that the fluid from the injured part failed even to lower the blood pressure of another animal.

It has been suggested by Scudder and his associates that potassium derived from disintegrated cells of the injured tissues is the responsible toxic factor. The blood potassium may rise to double or more than double the normal value in shock, especially in the later stages. Nevertheless, potassium does not appear to be a primary or major factor in the development of the shock state. Manery and Solandt found that the fatal level of blood potassium was many times higher than that seen in animals dying of shock.

The theory of local fluid loss

The toxemic theory of shock has been seriously questioned within recent years, notably by Blalock and his associates, by Parsons and Phemister, by Simonart of Belgium and several others. Blalock claims that the reduction in blood volume and consequent fall in blood pressure can be entirely accounted for by the escape of blood or of plasma from the vessels *at the site of the trauma*. He concludes that a circulating toxic substance does not exist and that transudation of fluid from vessels beyond the tissues directly injured does not occur. He bases his conclusions upon the finding that after bruising a limb by beating it with a hammer the quantity of blood fluid which accumulates within the part, as estimated by comparing its weight with that of the sound limb, is sufficient to cause the fall in blood pressure. In some experiments as much as a third or a half of the total blood volume was calculated to have entered the traumatized area. The loss of this amount of circulating fluid in itself is sufficient to cause death. From their results Blalock and his

followers conclude that there is no essential distinction to be drawn between shock and hemorrhage.

A discussion of the foregoing theories. Several types of injury lead to a condition of falling blood pressure and collapse which we know by the name of secondary shock. Many observers have gone on the assumption that this state, as seen clinically and as produced in animals by different means, has a common underlying cause. This is probably far from the truth. The mode of production of the shock state may be quite different according to the type of injury (mechanical, thermal, etc.). Since the end result, i.e., the state of shock, when fully developed is so similar as judged by the criteria at our disposal, it becomes necessary in any discussion as to causation to specify the type of injury which has been sustained. The present discussion is concerned solely with shock caused by mechanical trauma.

Decisive evidence for either of the theories outlined in the last two sections is lacking. In order to prove the toxemic theory it would be necessary to obtain from the injured tissues or from the blood issuing from them, a toxic substance which upon injection into a normal animal would reproduce the main features of shock. Such evidence has not been secured. Attractive in its simplicity as is the theory of local fluid loss, it fails to conform to several facts. It is true that in many instances the quantity of circulating fluid lost locally is sufficient to reduce the blood volume to the fatal level, but in other instances the fluid lost locally is *not* sufficient in amount to account for death. An animal may die after a mechanical injury with a fluid loss considerably less in amount than that which would be expected to be lethal, had the loss been due to frank hemorrhage. Such instances weigh more heavily against the theory than the other cases argue for it. In other words, the loss of an amount of circulating fluid locally which in itself could be taken as the cause of death does not exclude the possible co-existence of another lethal factor, and when death occurs with a fluid loss *less* than that which would prove fatal if lost by external hemorrhage, then another factor must be sought. There appears to be a "shock factor" quite distinct from the effect of the local loss of circulating fluid.

If it were true that the mode of death in shock and in hemorrhage are essentially and fundamentally the same, blood transfusion should prove equally effective in both conditions. On the contrary, whereas the fall in blood pressure due to hemorrhage is quickly restored to normal by

blood transfusion and is usually well maintained, in shock due to mechanical trauma the beneficial effects of transfusion are as a rule of short duration. The blood pressure is restored for a time but declines again to the shock level. The contrast between the effects of transfusion in hemorrhage and in shock has been pointed out by Moon as well as by several other observers, and has been observed by Taylor and Moorhouse in animal experiments. Taylor and Drummond, from observations upon wounded soldiers in France during the first World War have stated that only those in whom hemorrhage was a major factor gave a satisfactory response to transfusion. In cases of shock accompanied by little hemorrhage, transfusion was not of much benefit. Another difference between hemorrhage and shock is that in the former, dilution of the blood follows promptly, whereas in the latter the tendency is towards hemoconcentration. Attention has been drawn to other dissimilarities between the two conditions by Moon.

A dogmatic statement as to the fundamental cause of shock following mechanical injury is not warranted at the present time. Hemorrhage either external or into the damaged tissues is undoubtedly a contributory factor in many instances, in others nervous influences may play a part. Though it has been difficult to obtain direct evidence of a circulating toxic agent, the possibility if not the probability of such being responsible cannot be ignored.

A consideration of possible nervous factors in the development of traumatic shock

Cannon, though not discarding the toxemic theory, agrees that all cases of secondary shock cannot be so explained. He suggests that in certain instances the primary cause is overstimulation of the sympatho-adrenal system by sensory nerve impulses. Freeman, working in Cannon's laboratory, found that the continuous injection of adrenaline in physiological dosage (0.001 to 0.006 mg. per kilogram of body weight per minute) over a period of two hours caused a fall in plasma volume of from 10 to 29.5 per cent. A reduction in blood pressure to considerably below the normal level occurred upon stopping the injection. Adrenaline, as we know, causes vasoconstriction of the splanchnic and cutaneous areas and dilatation of the vessels of the skeletal muscles (p. 686). The prolonged arteriolar constriction in the cutaneous and splanchnic areas, it is conceived, by inducing asphyxia of the capillary walls renders them more permeable. The vasodilatation in the muscles by increasing the capillary filtration pressure will increase transudation of fluid in these situations. Other conditions, such as "sham rage," which excite the sympatho-adrenal mechanism were also found to

reduce the blood volume (by from 11 to 35 per cent) and cause a fall in blood pressure (to 60 mm. Hg). Sham rage induced after the removal of the sympathetic chains does not cause either a reduction in blood volume or a fall in blood pressure.

The experiments of Simonart mentioned above also indicate a nervous factor in the development of shock. The researches of O'Shaughnessy and Slome point in the same direction. These workers, while unable to obtain any evidence for the existence of a circulating toxin, found that blocking the nervous pathways by spinal anesthesia delayed or prevented the onset of shock in animals whose limbs had been traumatized. They, therefore believe that, though blood loss into the injured tissues plays a part in the development of shock, nervous influences dominate the picture.

The *treatment* of traumatic shock resolves itself into a correction of the abnormal physiology indicated in the foregoing discussion, namely, the restoration of the circulating blood volume by blood transfusion, the administration of fluids and the protection of the patient from cold, pain, anxiety and apprehension. Overheating the patient by means of hot water bottles or radiant heat is to be avoided since it induces dilatation of superficial vessels and thus increases the capacity of the vascular bed. The use of agents, e.g., pituitrin, which constrict the capillary vessels, is indicated. Adrenaline is of little or no value; its effect is evanescent and is exerted mainly on the arterioles whose tone in shock is already high.

Burn shock. An extensive burn may cause death from primary shock which follows almost immediately after the injury has been received, from secondary shock which supervenes in from 2 to 6 hours after the burning, or from toxemia which develops in from 48 to 72 hours. We are concerned here only with the cause of secondary shock due to burns.

An outstanding feature of burn shock wherein it differs from shock caused by mechanical injury is the extreme degree of hemoconcentration which occurs as a result of plasma lost from the burned surface and into the tissues surrounding the burn. In an extensive burn, according to Underhill, 70 per cent of the total plasma volume may be lost from the circulation within a few hours. The shock state following burns is attributed by many observers largely to the reduction in blood volume and to the increased viscosity of the blood. Harkins estimated the fluid loss by burning one side of an animal while it was on a weighing device which tipped towards the burned side as fluid accumulated. The average amount of fluid lost as measured in this way was 2.2 per cent of the body weight. The increase in weight of the

burned side commenced almost immediately following the burning and continued at a rapid rate for some time. The blood pressure, however, remained near the normal level until a short time before death, when it collapsed rather suddenly.

The question of a *toxic factor* in burn shock is confused for the reason that a distinction has not always been drawn between the stage of shock and the later stage of toxemia which results from the absorption of proteolytic products derived from the burnt tissues or of bacterial origin. Robertson and Boyd were among the first to investigate the question of a burn toxin. They reported that an alcoholic extract of burned skin but not of normal skin contained a toxic agent which caused death when injected into normal animals. The blood or red cells, but not the plasma, of burned animals also contained the toxic agent. They concluded that a toxin formed in the burned tissues was absorbed into the blood stream and carried by the red cells. Vogt also reported that if a burned area of skin from one animal (guinea pig) were excised and transplanted to another, the first animal survived but the second died. This experiment, however, as well as those of Robertson and Boyd, is pertinent rather to the question of burn toxemia which occurs at a later stage than to the development of shock itself. The finding of a high concentration of histamine in the blood of burned patients has revived the question of a toxic factor in burn shock. Barsoum and Gaddum determined the histamine concentration of the blood in a number of patients suffering from extensive burns and found it several times higher than the normal. However, no clear correlation in time between the histamine concentration in the blood and the onset of shock was found. Rose and Brown observed that the course of the blood histamine concentration following burns could be divided into three stages, (1) an early increase; this was not invariable, (2) a marked decrease during the period of edema and plasma loss, i.e., *during the stage of secondary shock*, and (3) a return to normal or above normal as the edema subsides and the patient is improving. It would not appear from these results that histamine is the responsible agent in the development of shock following burns.

Certain changes found at autopsy in burned subjects, e.g., damage to liver and kidney and intestinal ulceration have suggested a toxic factor to many, but such findings are probably associated with the toxemic stage rather than with the stage of shock.

The most effective measure for combatting burn shock is the transfusion of large volumes of plasma or serum (up to 5000 cc. in 24 hours) or a suitable substitute, with the object of restoring the blood volume and coincidentally of reducing the hemoconcentration. Benefit has been reported by some observers (e.g., Wilson; Rhoades; Lee and their colleagues) from the use of adrenal cortical extracts. The cortical hormone is said to decrease capillary permeability and thereby to reduce the plasma loss.

The "Crush syndrome." A person who has had a limb held and compressed for some hours by a heavy object such as a beam or a pile of rubble may pass into a state resembling shock some time after he has been released and removed to hospital. A number of such cases have been reported in England following air raids. But a closer study has revealed that they do not present the typical features of wound shock; death has been due to uremia. The part after its release may not appear to be severely damaged and the patients seemed at first to do well after reaching hospital. Marked edema of the limb developed later, accompanied by oliguria. The urine is brownish in color and contains dark granular casts; it gives the benzidine reaction due to the presence of myoglobin (p. 43) derived from the damaged muscles. Complete suppression of urine ultimately supervenes. The condition has been studied by Bywaters and his associates, who attribute the renal effects to blockage of the tubules of the kidney by myohematin. The anuria is therefore caused in a manner analogous to that resulting from the transfusion of incompatible blood (p. 35), the difference being that in one the pigment is liberated from muscle, in the other from hemolysed erythrocytes.

Attempts to reproduce the "crush syndrome" in animals have not been entirely successful. When both hind limbs of an animal such as the dog are made ischemic by compression for three or four hours and the limbs then released, the parts become swollen and a steady fall in blood pressure follows. Death occurs within a few hours. There is a rise in the non-protein nitrogen of the blood and there may be the passage of blood-stained urine before death. In experiments upon cats Eggleton found that an extract prepared from the affected muscles caused impairment of renal function (reduction of creatinine clearance) when injected into normal animals.

Blast injury. The explosive blast of a bomb or shell may cause death without any sign of external injury. But hemorrhages into the lungs, beneath the pleura or into the tissues of the liver and other abdominal viscera may be found at autopsy. Actual laceration of pulmonary tissue or of the abdominal organs may occur. The effects of blast have been studied experimentally by Barcroft and by Zuckerman. Barcroft attributes the pulmonary trauma to the sudden distension of the lungs and the rupture of the lung tissue

by the blast of air caused by the explosion. Zuckerman believes it to be due to the impact of the percussion wave set up by the explosion upon the body surface. The first theory does not explain the abdominal lesions that are so frequently observed. Nor is the second theory able to explain satisfactorily the pulmonary lesions, for one would expect the thoracic walls to protect the lungs from the force of the blast. It is probable that, in most instances, both factors play a part in blast injuries.

Anaphylaxis, Anaphylactic shock

The anaphylactic reaction is one which follows the administration of a foreign substance (most frequently protein in nature) to an animal which has been sensitized to it by a previous dose. It is one of the manifestations of an antigen-antibody response. In the dog and guinea pig, an interval of from 12 to 14 days must elapse between the two doses, in order that the maximum effects of the second dose may be produced.

The anaphylactic reaction, which in its severer manifestations is called anaphylactic shock, shows pronounced species differences. *In the dog* it is marked by dyspnea, vomiting, diarrhea, salivation, a profound fall in blood pressure ending in circulatory failure and death. The hepatic veins are strongly constricted, the liver and intestinal vessels are engorged and there is an increased flow of lymph from the thoracic duct. The blood is incoagulable as a result of the liberation of heparin from the liver (Markowitz and associates). The histamine content of the liver of sensitized animals is increased, but is reduced below the normal in anaphylaxis. Thus, the major symptoms of anaphylactic shock in the dog are centered in the liver. Nevertheless, many of the features of anaphylactic shock can be produced in the hepatectomized dog. *In the guinea pig*, the anaphylactic reaction consists of a powerful contraction of the muscles of the bronchioles. There is extreme dyspnea; death is due to asphyxia. The effect can be demonstrated in the perfused isolated lungs of a sensitized animal by the addition of the antigen to the perfusion fluid. The histamine content of the blood and lungs is increased to several times the normal.

In the rabbit, the reaction may be general or purely local. When the foreign substance is injected subcutaneously, the skin and subcutaneous tissue at the site of the injection become edematous and swollen; a sterile abscess or slough appears. This was originally described by Arthus and is known as the Arthus phenomenon. When the antigen is administered intravenously, the blood pressure falls abruptly, the respirations become rapid, but there is no dyspnea. The bladder and intestine are evacuated. The animal may die within a few minutes from dilatation and failure of the right ventricle. The failure of the heart is secondary to the increased resistance in the pulmonary circuit caused by constriction of the arterioles. The arterioles in other parts of the vascular system are also constricted and emboli composed of clumps of leucocytes may be

seen blocking the pulmonary and systemic capillaries. This, no doubt, accounts for the leucopenia which is found in the peripheral blood stream.

The evidence indicates, with little doubt, that the antibody-antigen reaction takes place in the tissue cells and not in the blood plasma. Dale showed, for example, that when the uterus was removed from a sensitized guinea pig and its vessels freed from all traces of blood, it gave the typical anaphylactic contraction, when the antigen was added to the bath in which it was immersed. Manwaring also found that the blood of the sensitized animal could be replaced by blood from a normal animal without affecting the first animal's sensitivity. Sensitivity can be passively transferred by the injection of the serum of a sensitized animal into a normal animal. A latent period elapses between the injection and the development of the passive sensitization which is presumably required for the fixation to the tissue cells of the antibody transferred in the injected blood. The interval of from 12 to 14 days, as mentioned above, which must elapse in order for the maximum effects of the antigen to become manifest is used, presumably, for the production of the antibody and its attachment to the tissue cells.

It is now generally accepted that the antigen-antibody reaction in some way brings about the liberation of histamine by the affected tissues and that the action of this amine is responsible for the anaphylactic manifestations. Practically all the features, as seen in these three species, can be explained upon such a basis. In the dog and guinea pig, the anaphylactic reaction is associated with a rise in the histamine concentration of the blood and, although the whole blood of the rabbit shows no increase and is often reduced, the amine passes from the white cells (which contain it in especially large amounts) into the plasma. The species peculiarities of the anaphylactic manifestations can be accounted for largely by the amount of smooth muscle in the reactive tissues of these three species and by its susceptibility to the action of histamine. In the dog, the smooth muscle of the hepatic veins is especially well developed. In the guinea pig, the bronchioles are particularly susceptible to stimulation by histamine and, in the rabbit, the pulmonary arterioles show unusually thick muscular coats.

Peptone solution, injected intravenously, produces in the dog effects almost identical with those of anaphylactic shock, including incoagulability of the blood due to the liberation of heparin by the liver. Sensitization by a previous dose is not necessary, however. In man, fatal anaphylactic shock may follow the injection of horse serum into a person who has been sensitized by a previous administration. Allergic reactions, in general, show many similarities to anaphylactic reactions and many observations suggest that the two are fundamentally allied, although in the case of allergic reactions, sensitization by an earlier exposure is apparently not required, the reaction appearing upon the first known contact with the foreign substance.

CHAPTER XXVIII

SPECIAL FEATURES OF THE CIRCULATION IN DIFFERENT REGIONS

THE CAPILLARY CIRCULATION

The term *capillary vessels* will be employed to include all the purely endothelial tubing which lies between the arterioles on the one hand and the small veins on the other.

The observations of several investigators in the past have pointed to the capillaries being capable of regulating their size quite independently of the state of the arterioles which feed them. Stricker (1865), for example, saw active contractions and dilatations of capillaries in the nictitating membrane of the frog. Roy and Brown found that individual capillaries lying close together and apparently supplied with blood from a common arteriole required different pressures to obliterate their respective lumina. Steinach and Kahn obtained more direct evidence of independent capillary movements by electrical stimulation of excised tissues (nictitating membrane of the frog and mesentery of the cat). Constriction of individual capillaries was clearly demonstrated. These observers also reported that stimulation of the cervical sympathetic in the living animal caused contraction of the capillary walls in an area *from which the circulation had been occluded*. Scant attention apparently was paid to these observations. Until the more recent work of Lewis and of Krogh and their associates, few physiologists believed that *active* changes in capillary diameters could occur. The capillaries were considered to play a purely *passive* rôle; changes in their capacity were believed to depend entirely upon the distension or collapse of their elastic walls in strict accordance with the diameters of the arterioles at the moment, and consequently upon the quantity of blood which they received from the arterial side.

This view is now admitted to be wrong and the independence of capillary movement is firmly established. The evidence will be briefly cited.

(1) Cotton, Slade and Lewis showed that reddening of the skin of the arm could be induced by mechanical stimulation, after the circulation had been arrested by means of a blood pressure cuff. The dilatation of the superficial vessels, it was argued, must have been the result of relaxation of the capillary wall and not of passive distension, since after the blood in the part had

become stagnant, and venous and arterial pressures equal, arteriolar dilatation would have drained blood from, rather than forced it into the capillaries. A white line was also obtained upon drawing a point lightly over the skin, which would only be satisfactorily explained by capillary constriction. (2) Krogh observed the capillaries in the tongue muscles of the frog beneath the microscope, and showed that they contracted when stimulated mechanically, as by touching them with a stiff hair. Dilatation could be induced toward the venous end of the capillary while the diameter of the arterial end remained unaltered, the dilated vessel filled from the vein. Drawing the hair along the capillary toward the arteriole was followed by a progressive opening up and filling of the former vessel. As the dilatation reached the arteriole the arterial blood was admitted and the flow in the capillary became reversed. (3) When the arteries to the frog's tongue were occluded, active dilatation of the capillaries was induced by mechanical stimulation. If, on the other hand, the capillaries were constricted they remained so, against an arterial pressure of several millimeters of mercury. Lewis also showed that the capillaries of the human skin were capable of remaining contracted against an arterial pressure of approximately 100 mm. of mercury. (4) Various chemical substances, e.g., acids (lactic, CO_2), urethane, iodine, cocaine, silver nitrate and chloroform cause dilatation of the capillaries; some of these, e.g., urethane and iodine, have no effect upon the arterioles. Alkalis and oxygen cause capillary constriction. Though adrenaline (in ordinary dosage) causes constriction of both arterioles and capillaries in man, in the frog the arterioles are constricted while the capillaries are often simultaneously dilated. Histamine induces dilatation of both types of vessels in man but, as shown by Dale and Richards, causes arteriolar constriction and capillary dilatation in the cat. Acetylcholine and adrenaline applied directly to the arterioles cause dilatation and constriction, respectively, yet, during these arteriolar changes, scarcely noticeable alterations in capillary diameters occur.

The results of a sufficient number of experiments have been cited to show that there is no reason for doubting the independent regulation of the capillary circulation.

Spontaneous changes in capillary diameters

Krogh found that there was a great variation in the number of capillaries which might be pervious at a given moment. The number of patent vessels was directly related to the activity

of the tissue at the time, the number of open vessels being much fewer in resting than in active muscle. When, for example, India ink was injected into the vessels and portions of tissue excised before and after excitation, the increase in number of open vessels in the latter instance was very striking. The resting muscle in the intact animal is pale and only relatively few vessels can be seen. Others may be observed to be contracted to such small diameters that a red cell is unable to enter the narrowed channel without

changed, capillaries hitherto invisible, since their lumina apparently had been obliterated by tonic contraction, sprang into view, while other vessels which had been partially closed dilated fully. Krogh considers that these changes play an important rôle in the mechanism for the regulation of the oxygen supply to the tissues. During rest a comparatively large area of tissue is fed with blood from a single central capillary. During activity, as more capillaries become patent, the area of tissue supplied by each vessel becomes correspondingly reduced (see fig. 150, p. 323). Richards also observed a great increase in the number of capillary tufts in the frog's kidney, when the activity of the organ increased (see p. 387). From these observations upon frog's muscle and kidney, conclusions cannot, however, be drawn regarding the blood supply to tissue in general, since Lewis has found that, in the human skin at any rate, the capillary pattern changes very little from time to time; all the vessels are open whether the blood flow is small or large. Lewis concludes that augmentation of the blood flow through the skin is brought about through the greater dilatation of pre-existing channels rather than by the opening of capillaries that had been previously closed.¹

The elements in the capillary wall responsible for their independent movements

Since the capillaries are devoid of muscle fibers, the question naturally arises concerning the means by which their contraction and relaxation are brought about. The endothelial cells themselves, either through actual contraction or by swelling, appear to be responsible for the alterations in capillary diameters. The Rouget cells (p. 112) found in relation to the capillary wall in amphibians are not, as was previously believed, concerned in the reactions. Clark and Clark give evidence for the Rouget cells being simply wandering connective tissue elements which have come to rest upon the capillary wall. They have observed movements of the endothelial wall independently of the Rouget cells, and Florey and Carleton describe cells in mammals which are probably analogous to Rouget cells, but think that they are too few in number to be of any importance in the capillary movements. More-

¹ Bordley and associates disagree with this conclusion, for they observed intermittency of flow in the capillaries of the skin over the tibia. Even two capillaries arising from a single arteriole were seen to alternate with one another in permitting the passage of corpuscles.

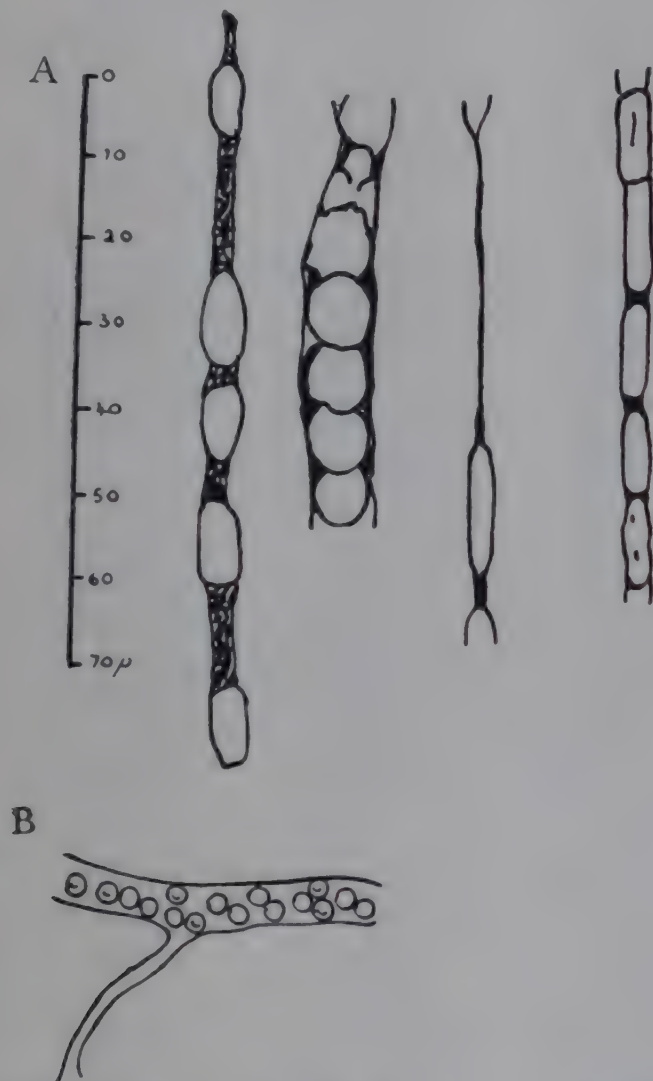

FIG. 116. A, muscle capillaries of guinea-pig vitally injected with India ink. Blank oval areas represent red cells, most of which are distorted in shape. B, illustrates "plasma skimming." (After Krogh.)

becoming squeezed out of shape. A cell pressed into a elongated or sausage-like form could frequently be seen within the vessel or, in some instances, imprisoned by the complete closure of the capillary lumen at each end (fig. 116A). In other instances, constriction of the vessel excludes the corpuscles entirely from a neighboring capillary channel, the plasma alone being permitted to enter. This phenomenon has been termed "plasma skimming" (fig. 116B). Upon stimulating the muscle the picture was entirely

over, they state that a clear space separates these cells from the capillary wall. The Rouget cells are probably reticulo-endothelial elements.

THE INNERVATION OF THE CAPILLARIES

EFFERENT FIBERS. Non-medullated nerve filaments were observed by Woollard accompanying the capillaries. They form a loose investment of the vessels, but none was seen to end actually upon the capillary wall. These nerves are derived from the sympathetic and are extensions from the periarteriolar plexus (p. 232); they degenerate after removal of the sympathetic chain. Physiological evidence for constrictor fibers to the capillaries has been obtained by several workers. The observations of Steinach and Kahn have been mentioned (p. 264). Hooker obtained contraction of the capillaries of the ear upon stimulation of the cervical sympathetic in the cat, which he concluded was a direct effect upon the vessels. Marvin and Harris obtained similar results, but excluded more certainly any possibility of a passive effect upon the capillaries as a result of arteriolar constriction by arresting the circulation to the rabbit's ear before applying the stimulus. Krogh and his colleagues observed contraction of the capillaries of the frog's web when sympathetic fibers were stimulated. Excision of the abdominal sympathetic ganglia, on the other hand, or section of the sciatic, by removing constrictor tone, caused the capillaries of the web to dilate.

Dilatation of muscle capillaries is probably mainly dependent upon the production of acid metabolites, though it is possible that they also, like the arterioles, are dilated through the medium of sympathetic fibers (p. 234).

Engel postulates a permeability-controlling function for the sympathetic based upon experiments in which the vessels of the knee joint were perfused with a dye-containing fluid. Sympathetic stimulation was found to increase, sympathectomy to decrease the excretion of dye into the joint cavity.

AFFERENT FIBERS. Woollard observed *medullated* fibers reaching as far as the arterioles but no farther. They were seen to end by collateral branches in the arteriolar wall on the one hand, and in the adjacent subcutaneous tissue on the other. Some of the latter were seen to terminate in Pacinian corpuscles (p. 801). These medullated fibers are sensory and probably provide the basis for axon reflexes; they probably also convey antidromic dilator impulses from the

central nervous system. Doi, for example, caused full dilatation of the arterioles in the frog by means of acetylcholine; upon then stimulating the posterior nerve roots dilatation of the capillaries was observed. Since the blood flow through the arterioles was already maximal the dilatation could not have been simply a passive effect. This observation has been confirmed by Krogh and his associates who also obtained dilatation of capillaries in the frog's tongue upon mechanical stimulation of the peripheral end of the glosso-pharyngeal. The failure, however, to demonstrate sensory fibers ending upon the capillary wall lends support to the view of Lewis that the dilatation of the cutaneous capillaries is brought about through the intermediary of a chemical substance (H-substance, p. 269) liberated at the nerve ending. Stohr also states that a nerve fiber can be traced to the vicinity of only one out of every hundred capillaries, yet all dilate as a result of nerve stimulation. This, of course, is an indication that vessels more remote from the nerve terminal are acted upon by a diffusible chemical substance liberated by the latter.

THE VASCULAR REACTIONS OF THE HUMAN SKIN

The arterioles of the skin upon approaching the bases of the papillae (i.e., the layer of true skin immediately underlying the epidermis) turn horizontally, lose their muscular coats and give rise to hairpin-shaped endothelial tubes—the *capillary loops*. The proximal or arterial limb of the capillary loop ascends in the papilla and then turns upon itself to form the venous limb. The latter on reaching the base of the papilla joins with the venous limbs of neighboring loops to form a *collecting venule*. The collecting venules anastomose with one another to form a rich plexus—the *subpapillary venous plexus*—which runs horizontally beneath the bases of the papilla. It drains into deeper veins.

The capillary loops, collecting venules and subpapillary venous plexus are formed of simple endothelial tubing and may therefore be referred to as the capillary system of the skin. The walls of the arterioles and deeper venules contain smooth muscle.

The capillary loops, as Lombard first demonstrated, can be seen readily in the living skin under the low power of the microscope. A drop of cedar or paraffin oil is placed upon the skin at the base of the finger nail or other region where the epidermis is thin. The area under observa-

tion is illuminated by a powerful beam of light (fig. 117). If the horny layer be removed by blistering, the vessels are rendered more distinct. Under favorable circumstances the vessels of the subpapillary venous plexus and even deeper vessels may also come into view.

The capillary circulation in relation to the color and temperature of the skin

The color of the skin may afford important diagnostic information, and the factors underlying the variations in the tint and depth of color are of considerable interest from a purely physiological point of view. Lewis has made an extended study of the capillaries of the human skin and their reactions to various types of stimulus. The color of the skin is not dependent normally upon

still be seen; subsequent occlusion of the capillary loops did not increase the pallor appreciably.

When the skin is unusually pale and little blood is contained in the superficial vessels (subpapillary venous plexus) the skin is more transparent, and the deeper venous plexuses then contribute largely to the color of the skin, often adding a leaden tint to the pallor. When the overlying vessels are open and the skin is well supplied with blood these deeper vessels are hidden from view.

Apart from pigmentary effects and assuming the general arterial blood to be normal, the *color* of the skin, i.e., the dominance of the reddish or of the bluish hue depends upon the extent to which the oxyhemoglobin becomes reduced during the passage of the blood through the cutaneous vessels. The degree of reduction will depend entirely, as a rule, upon the rate of blood flow. When the flow is rapid or slow the blood is, respectively, more arterial or more venous in character. The tint of the skin varies accordingly.

The *depth* of the skin color, i.e., its intensity apart from its hue is dependent upon the diameters and the degree of engorgement with blood of the superficial vessels.

So, taking into account both the hue and the depth of color, an intense scarlet color of the skin indicates a normal or increased blood flow and dilated vessels; a deep blue color (see cyanosis, p. 372) accompanies a slowed blood flow and dilated vessels (such as may result from obstruction to the venous trunks). Pallor or a light pink color of the skin is seen when the vessels are constricted or of moderate tone, and the blood flow normal or rapid. A slowed cutaneous blood flow and constricted superficial vessels tend to produce a leaden or ashen type of cyanosis for, as mentioned above, the dark blood in the deeper venous plexuses then becomes faintly visible.

The *temperature* of the skin depends largely upon the rate of blood flow through its vessels. The radiation of the body's heat is carried out principally through the medium of the cutaneous vessels (p. 624). The warmer blood of deeper regions is diverted through the cutaneous channels and becomes cooled in its passage. So the cyanotic skin (due to reduced cutaneous blood flow) is usually cool, and the flushed, scarlet skin hot. But the skin may be pale with constricted superficial vessels and yet radiate a large quantity of heat, if the blood flow through deeper vessels is rapid. Sometimes such a pale skin is hotter than another of a redder color. In the former instance, heat from the swiftly flowing blood

FIG. 117. The bed of the finger nail in a healthy subject, showing the capillary loops and the summits of the skin papillae. The size of the structures is indicated by the $\frac{1}{16}$ mm. scale. (After Lewis.)

the most superficial vessels, i.e., the capillary loops, but upon the subpapillary venous plexus. The vessels of the plexus, though more deeply placed, present a greater area parallel to the skin, whereas the capillary loops are disposed chiefly at right angles to the skin surface. A simple experiment devised by Lewis illustrates the predominant rôle played by the subpapillary venous plexus in determining the skin color. When the superficial vessels were observed beneath the microscope through a glass slide, it was found that as the slide was gradually pressed down upon the skin the venous plexus collapsed first; not until further pressure was applied were the capillary loops obliterated. Blanching of the skin occurred, nevertheless, at the moment when the blood was pressed from the plexus and while the capillary loops could

in the deeper vessels is simply conducted through the overlying skin and dissipated from the surface through radiation and convection.

Vascular responses of the skin to stimulation by mechanical and other agencies

THE WHITE REACTION. If the surface of the skin be stroked lightly with a blunt "pointed" instrument, a line of pallor appears in from 15 to 20 seconds which traces the path taken by the instrument. The line attains its maximal intensity in from a half to 1 minute, and then gradually fades to disappear in from 3 to 5 minutes. This *white reaction* must not be confused with the white trail which follows *immediately* in the wake of the instrument and is due simply to the expression of blood from the vessels by the instrument. The white reaction proper is due to *direct stimulation of the capillary wall and has not a nervous basis*. It has been shown by Lewis to be due to the tension exerted upon the walls of the minute vessels—capillary loops, collecting venules and subpapillary venous plexus—which respond to the stimulus by contraction. The sharply delineated character of the white line, and the fact that it can be obtained after the circulation through the region has been occluded by compression of the larger vessels, show that it is an active capillary response, and not the result of arteriolar constriction. The contractile force exerted by the capillary wall is such that it is capable of resisting a pressure of from 50 to 100 mm. Hg. In other words, the capillaries can remain contracted in the face of any pressure that could normally reach them through the arterioles.

THE TRIPLE RESPONSE. This comprises: (1) *the red reaction*, (2) *the flare*, and (3) *the wheal*.

(1) *The red reaction.* If the pointed instrument be drawn more firmly across the skin, especially of the forearm or back, a red instead of a white band appears after a somewhat shorter latent period (3 to 15 seconds), reaches its maximum in from a half to one minute, and then gradually fades. The time of its disappearance is variable; this may occur in a few minutes or be postponed for half an hour or more. It can be seen to assume a bluish tinge before it fades. Like the white reaction it is strictly localized to the line of stroke; it is due to *dilatation* of the capillaries. The red reaction can be induced in its full intensity in the skin from which the circulation has been occluded, so it is due to active dilatation of the minute vessels and is not a passive result of arteriolar dilatation (see p. 264). By means of a

thermocouple placed upon the red line a rise in temperature indicating increased blood flow may sometimes be detected. *The red reaction is not dependent upon nervous mechanisms since it occurs after section and degeneration of the cutaneous nerves.*

Pale lines bordering the central red band can frequently be seen. These are due to capillary contraction resulting from tension exerted upon the skin on either side of the line of stroke. The white halo is identical in every way, e.g., latency, duration and causation, with the white reaction described above. A certain diagnostic importance, quite unjustified, has in the past been attached to the red reaction with pale borders. It was spoken of as the *tache cérébrale*, or as *Trousseau's phenomenon*, and was believed to signify the existence of certain meningeal or cerebral lesions. It is, however, a perfectly normal response to mechanical stimulation.

(2) *The spreading flush or flare.* If the stimulus is unusually strong, or is repeated often enough, the reddening of the skin is not confined to the line of stroke but surrounds it for a variable distance (1 to 10 cm.) according to the intensity of the injury inflicted. The temperature in the suffused area is definitely raised. This flare reaction appears a few seconds (15 to 30) after the local red line, and fades sooner but remains a bright arterial color throughout. It is due to dilatation of the arterioles, since it does not appear after the circulation of the part has been occluded by means of a tourniquet; also, unlike the red reaction, *the flare is dependent upon local nervous mechanisms (axon reflex)*. *It occurs after the nerves are divided but not after they have degenerated.*

(3) *Local edema or wheal.* When the stimulus is still more intense the skin along the line of the injury becomes blanched and raised above the surrounding area to a height of 1 or 2 mm. or even more. Such a wheal or welt is commonly produced in a normal person by the lash of a whip and other types of strong localized stimulation. The circular wheals of an urticarial rash (hives), are similar in character. In susceptible individuals, even light stimulation, such as drawing a pencil with moderate pressure over the skin of the back, will produce linear wheals surrounded by a diffuse red halo along the pencil's track. In this way letters or other designs may be embossed upon the skin (fig. 118). This phenomenon, which is spoken of as *dermographism* or *facitious urticaria*, has been considered pathological, though actually it can be demonstrated to a greater or less degree in many young and perfectly healthy individuals, and can be elicited

in some degree by repeatedly stroking the skin of the back of almost any normal person.

The wheal is preceded by and completely replaces the usual red reaction. It makes its appearance in from 1 to 3 minutes from the time of injury and is at its maximum height in 3 or 5 minutes. It is surrounded by the flare described above. The raised patch at first is clearly cut, but as time passes it increases in diameter and decreases in height, loses its sharpness and finally, though perhaps not for some hours, disappears. The wheal is due to the transudation of fluid from the minute vessels involved previously in the red reaction; it is, therefore, a localized edema. The gradual reduction in height and sharpness of the wheal and its final disappearance are due to the diffusion of the exuded fluid into a wider area of skin. Sometimes the fluid collects beneath the horny layer of the skin and strips it from the

FIG. 118. Dermographism (from Adami's textbook of Pathology, after Hyde and Ormsby).

underlying epidermis. Such a collection of transuded fluid constitutes a blister.

Increased permeability of the capillary wall is judged to be the immediate cause of the localized edema which constitutes the wheal. Increased intracapillary pressure, distension of the capillary lumen or reduction in pressure in extracapillary spaces have been shown by Lewis to be not responsible. Suction, for example, amounting to a negative pressure of 90 mm. Hg, applied to the surface of the skin over the line of the red reaction or over the area of the flare does not cause a wheal to form. Nor will the application of a positive pressure of 50 mm. Hg prevent its appearance. Increasing the intracapillary pressures by compressing the veins does not cause a wheal to form more readily along the track of a red reaction; as a matter of fact a wheal upon a congested area is less pronounced. That increased permeability rather than simply a rise in the filtration pressure, is the dominating feature is also manifest by the high protein content of the transuded fluid. This more nearly approaches that of blood serum than the fluid of ordinary edema.

Wheal production does not depend upon a nervous mechanism. Though an accompanying flare is not an essential feature of a wheal, since the phenomenon can be elicited in denervated skin, the red halo is nearly always present, and in normal skin the degree of whealing is usually proportional to the latter's intensity. When, for instance, the injury is inflicted while the circulation is occluded, so that the flare is prevented, the wheal does not appear until the circulation has been again restored. This simply means, however, that though increased capillary permeability has occurred during the period of occlusion, blood fluid is not available in sufficient quantity for the production of the edematous swelling.

H-substance

A considerable weight of indirect evidence has been presented by Lewis to support the conception that a diffusible substance is responsible for the three reactions comprising the triple response. This material, which he calls *H-substance*, is thought to be liberated by the injured cells of the epidermis lying beneath the horny layer and superficial to the papillae. The possibility that more deeply lying tissues, when subjected to injury, may release the substance is not excluded, but a needle which does not penetrate beyond the epidermis elicits the typical threefold reaction. The chemical substance closely resembles *histamine* in its action. It apparently causes the red reaction and the wheal by a direct action upon the capillary wall. The flare is believed to be due to chemical stimulation of the sensory endings of the skin, thus bringing about arteriolar dilatation through the mechanism of the axon reflex (p. 247).

Though, as just pointed out, the evidence for this theory is indirect and actual proof of the existence of such a humoral mechanism is lacking, the results of Lewis's experiments carry conviction. The reader is referred to this author's original papers or to his monograph for the details of the various ingenious experiments performed, and the clear arguments set forth in support of his thesis. The evidence which has been brought forward can be no more than briefly cited here. The following is a summary:

(1) Histamine (1:1000 histamine phosphate) when pricked into the skin reproduces the triple response characteristic of mechanical injury. The individual reactions, local red reaction, wheal and flare produced by histamine are indistinguishable in all their features from those resulting from the various types of skin injury, pricking, scratching, freezing, burning, etc.

(2) Histamine can be extracted from many tissues of the body including the cells of the epidermis.

(3) An individual in whom the cutaneous reactions were readily produced was chosen and the circulation to the two arms occluded by means of a pneumatic armlet. A minute after circulatory arrest a stroke was made upon one arm, and on the other 9 minutes later. A typical flare resulted in each instance when the circulation was restored to both arms simultaneously. If the flares were due purely to a nervous mechanism, they should both fade at the end of the same interval of time following the application of the stimulus. That is, the second flare should disappear 9 minutes after the first. As a matter of fact they disappeared almost simultaneously. This observation though inexplicable

FIG. 119. Reactions caused by histamine and by injury (upper figure) in an urticarial subject. The vessels of the two arms were occluded. One minute later the left forearm was stroked (above) and a group of three histamine punctures (1 in 3,000 dilution) was laid down (below); 9 minutes later the right forearm was similarly and symmetrically treated; the vessels of both arms were released 10 minutes later i.e., at the 11th minute. The numbers outside the brackets indicate the times in minutes at which the contours were outlined after restoration of the circulation. The numbers within the brackets give the times elapsing after application of the stimuli. In the stroke figures the fading was followed until the redness became confined to the wheals. (After Lewis.)

upon a nervous basis conforms with the theory that the responsible agent is a chemical substance released by the injury. It also indicates that the chemical remains at the site of injury, its effect subsiding only after the blood flow to the skin has been restored. It is clear that if the flare is due to a released substance, then the same period of time will be required for the blood to wash away the material from the stimulated point in each arm. Identical results were obtained when, instead of a mechanical stimulus, histamine itself was pricked into the skin (fig. 119).

(4) Two wheals with their surrounding flares were made to appear upon the skin of the arm, one a short distance above the other. An elastic bandage was then wrapped tightly around the arm so as to cover the

lower wheal and the lower half of the corresponding flare. The lower half of this flare was in this way deprived of its circulation while its upper half was visible above the bandage. The entire circumference of the upper flare was beyond the margin of the bandage. The bandage was retained in position for 20 minutes. The upper flare was found to fade gradually and to disappear in the usual length of time. The visible part of the lower flare, however, retained its vivid hue throughout the period of occlusion and only upon removal of the bandage and the re-entry of blood into the lower half of the flare did fading commence. This result is interpreted as indicating that the released substance being retained in the occluded area exerted a persistent effect upon the nerve endings there, and through axon reflexes sustained the arteriolar dilatation in the unoccluded half.

(5) Lewis and Harmer found that when wheals were induced by stroking an extensive area of the back of a susceptible subject, generalized circulatory responses similar to those resulting from the hypodermic administration of histamine, namely, flushing of the face and other parts of the body surface, and a distinct fall in blood pressure resulted. The fluid drawn from urticarial wheals was also tested for a histamine-like action. The results, however, were not conclusive. Only in some instances could such an action be demonstrated. The fluid was also tested upon the guinea-pig's uterus, but again little light was thrown upon this question, for, though the fluid stimulated this organ to contraction, normal plasma caused a similar effect. More recently it has been shown that extensive stimulation of the skin of a susceptible person causes increased secretion of gastric juice. This is a well-known histamine effect (p. 442).

(6) An individual upon whose skin urticarial wheals can be provoked with unusual facility by stroking (dermographism) shows a sensitivity to histamine injections that is no higher than normal. This fact indicates that the susceptibility of such an individual does not depend upon a greater responsiveness of his capillary vessels. The greater readiness with which his skin reacts to mechanical stimulation is therefore attributed to an exaggerated sensitivity of the cells of the skin to injury and a more prompt release of a diffusible substance.

The cutaneous reactions following injuries of various sorts, e.g., burning, freezing, electrical stimulation and the more slowly-developed erythema resulting from ultra-violet irradiation, are believed to be produced by the same humoral mechanism. The cardinal signs of inflammation—redness, heat, and to some extent the swelling and pain—can be similarly explained, namely, direct action of the dilator H-substance upon the minute vessels, and an indirect effect through the medium of the axon reflex, upon the arterioles of the surrounding area.

Lewis has extended this conception to embrace the cutaneous vasodilator effects of antidromic impulses discharged under ordinary circumstances from the central nervous system through the posterior roots (p. 235). The nervous impulse, it is conceived, brings about its effect upon the vessels through the release of H-substance from the cells of the epidermis, and not by a direct action upon the vascular wall.

The cutaneous lesions characteristic of herpes zoster are ascribed to the liberation of H-substance from the epidermal cells by antidromic impulses. Head and Campbell have demonstrated inflammatory changes, hemorrhages and destruction of nerve cells in the posterior root ganglia. Similar skin changes may follow involvement of the roots by malignant disease or injuries, such as the so-called trophic ulcers accompanying lesions of the sensory side of the nervous system, e.g., along the course of lightning pains in tabes. The erythema and blistering of the skin induced by the suggestion of burning or other injury during the hypnotic state may possibly be produced in a similar manner. Also it is probable that many other types of cutaneous lesions familiar to the dermatologist, e.g., vesicles, urticaria, maculae, purpuric spots, etc., have a neuro-chemical basis.

It has been suggested by Dale that acetylcholine (p. 946) probably also plays a rôle in cutaneous vascular reactions. It is not unlikely that this substance is liberated at the nerve ending on the arteriole as a result of impulses either discharged antidromically from the central nervous system or arising peripherally and reaching the vessel along the path of an axon reflex. In the latter instance the cutaneous stimulus is conceived as causing the liberation of H-substance. This excites cutaneous nerve terminals, and the impulses thereby set up being transmitted to the nerve endings on the arteriole cause the release of acetylcholine. This conception would, therefore, hold acetylcholine directly responsible for the arteriolar dilatation characteristic of the flare.

REACTIVE HYPEREMIA AND BIER'S SPOTS. If the circulation to a part is arrested for a time (as by compression with a tourniquet or a sphygmomanometer armlet) and then released, the skin flushes, the volume of the part increases and the blood flow through it is greater than before the vessels were occluded. The hyperemic reaction occurs though all nerves supplying the part have been severed, and it has been shown by Lewis and Grant that it occurs independently of any nervous influence (e.g., axon reflexes). These observers furnish evidence that it is due to the accumula-

tion of H-substance in the skin during the period of circulatory arrest. It has also been demonstrated by Barsoum and Smirk that the concentration of a substance with the biological properties of histamine increases in the venous blood of the arm after a period (10 to 30 minutes) of circulatory arrest.

During the period of circulatory arrest the skin becomes mottled, blanched areas (Bier's spots) and bright blotches appearing on the background of cyanosis. The bright areas are caused by blood delivered through the nutrient arteries of the bones and anastomatic channels to the main vessels of the limb below the obstruction. This trickle of blood forces oxygenated blood from the occluded arteries into the cutaneous capillaries. The pallid areas, which were first described by Bier in 1898, are due to capillary contraction. A new significance has been given to the latter by the observations of Rous and Gilding, who found that they occur also in the skin and other non-vital tissues of animals when the blood volume is considerably reduced. These authors look upon the localized contraction of the vessels in such instances as part of the mechanism whereby the capacity of the circulatory system is reduced and the blood supply to vital tissues thus maintained at the expense of those of less importance.

CAPILLARY PULSATION

Rhythmical changes in skin color—flushing alternating with pallor corresponding to the heart beats—may occur when the smaller arterioles of the skin become dilated. It is seen in aortic regurgitation and in arteriovenous aneurysm, and is usually ascribed to the high pulse pressure characteristic of these conditions. Lewis, however, has shown that high pulse pressure, though it enhances the phenomenon, is not a necessary condition for its appearance, for it occurs also when the pulse pressure is low. The essential factor concerned in capillary pulsation is a certain degree of dilatation of the fine arterioles beneath the papillary layer of the skin. The opening of these vessels reduces the peripheral resistance and the flow in the capillary then tends to become intermittent instead of continuous (p. 123). Pulsation in the capillaries may be demonstrated in most normal young persons, especially if peripheral vasodilatation be induced by immersing the hand in hot water, or by means of a drug such as amyl nitrite, and then observing the skin through a glass slide pressed lightly upon it. The pulsation is seen particularly well in the more highly vascularized regions, e.g., the finger tips, the cheeks, lips or ear lobes, or on the outskirts of inflamed regions. It may frequently be demonstrated in certain of these regions in normal in-

dividuals, even without preliminary dilatation, and is especially evident under the low power of the microscope. In elderly persons, however, it may be impossible of demonstration, even after the application of heat, and then it is assumed that the vessels are incapable of the necessary degree of dilatation. The capillary loops, the collecting venules and the subpapillary venous

has been measured by Landis. A fine cannula was inserted into either limb of the loop as desired and the pressure measured directly by means of the apparatus shown in fig. 120. With the hand at or above the level of the auricle (level of the manubrium sterni) the capillary pressure remains constant but increases when the hand is moved to a lower level. The increase in pressure

FIG. 120. Diagram of apparatus for the determination of capillary pressure by micro-injection. C', C'', three-way stopcocks; H, holder of micromanipulator; M, mercury manometer; O, binocular microscope; S, syringe. The system is filled with physiological saline to which has been added 0.3 per cent sodium citrate as an anticoagulant. When the tubing (W) is closed at T the height of the mercury column indicates the pressure exerted upon the contents of the micropipette inserted into the capillary. By means of the syringe, the pressure in the system is adjusted until the corpuscles remain in the same general position in the tip of the pipette, oscillating back and forth with each heart beat. The reading of the manometer then gives the capillary pressure. (After Landis; Heart, 1930, 15, 209.)

TABLE 22*
Gradient of pressure in the capillary loop of skin of hand

plexus, i.e., those vessels responsible for skin color, are involved in the pulsation. Capillary pulsation cannot therefore be considered as an unequivocal indication of aortic regurgitation or other pathological condition.

CAPILLARY PRESSURES

The blood pressure in the arterial and venous limbs of the capillary loops of the human finger

is in direct proportion to the distance between the new level and the base of the heart and is due to the hydrostatic pressure of the column of blood in the veins (p. 139). The average pressure in the arterial limb of the loop was found to be 32 mm. Hg, and in the venous limb 12 mm. Hg when the hand was at the level of the auricle. In the arterial limb the blood pressure was higher, in the venous limb lower, than the osmotic pressure of the plasma (see p. 42). The application of heat, venous congestion or the production of a histamine flare elevated the capillary pressures well above these values. The application of cold caused first a fall in pressure and then a small rise above the original pressure. The production of a wheal, as by freezing, resulted in a rise of the average pressure, in the arterial limb to 49 mm. Hg, and in the venous limb to 32 mm. Hg. In Raynaud's disease the pressure in the capillary loop is greatly reduced during the vascular spasm. (See Table 22.)

ARTERIO-VENOUS ANASTOMOSES

Grant and his associates have shown that in the ear of the rabbit, communications (20 to 70 micra in diameter) exist normally between the arterioles and corresponding venules (fig. 121) through which the blood may be shunted. They are also present in the human skin and in the toes of birds. At ordinary room temperature these anastomotic channels are closed, but they open when the air temperature rises or falls below a certain critical level. Local heating of the rabbit's ear does not cause dilatation until the temperature rises to between 35° and 40°C. Local cooling

FIG. 121. Reaction of anastomosis and associated vessels to lowering of body temperature. A^1 , A^2 , artery; AV, arterio-venous anastomosis; C, vein. Upper figure (a), anastomosis open; lower figure, (b), anastomosis closed. (After Grant.)

causes dilatation which commences when the temperature is reduced to below 15°C.; above this temperature the capillaries are constricted. At 5°C. the dilatation of the anastomotic channels is general. This reaction is brought about reflexly and is not confined to the portion of the ear actually cooled, but involves the whole member and even the ear of the opposite side. In man, the blood flow in the vessels of the terminal phalanges of the fingers may increase some 100 times, as a result of the reflex dilatation of arterio-venous anastomoses. The communicating channels are believed to have two important functions; (a)

regulation of the body's temperature by increasing the radiation of heat, since when dilated they permit an enormous quantity of blood to flow through the peripheral parts. The importance of this mechanism is evident from the fact that in the rabbit the body temperature can be raised or lowered at will by heating or cooling the ears. (b) Maintenance of the temperature of outlying parts of the body against local cooling.

The arterio-venous anastomoses are supplied by constrictor sympathetic nerves, and are constricted by adrenaline. They are dilated by mechanical stimuli, by the stimulation of sensory nerves and by histamine or acetylcholine. The reactions are therefore essentially the same as those of the arterioles. In man, similar channels have been demonstrated connecting the arterioles and veins of the terminal phalanges.

THE CORONARY CIRCULATION

The heart muscle is supplied with blood from the two coronary arteries, right and left, which arise directly from the aorta close to its origin. The *right coronary* artery appears between the roots of the pulmonary artery and aorta and curving to the right in the auriculo-ventricular groove runs toward the apex in the inferior (posterior) interventricular sulcus. The part of the vessel in the auriculo-ventricular groove is referred to as the right circumflex artery and that portion in the interventricular sulcus as the posterior descending branch. Though there is considerable variation in the distribution of the two coronary vessels, in the most common arrangement (48 per cent according to Schlesinger), the greater part of the heart receives branches from the right coronary artery which supplies all of the right ventricle, the posterior half of the interventricular septum and part of the left ventricle; a special branch goes in the majority of cases to the sino-auricular node, another to the auriculo-ventricular node and bundle.

In a smaller proportion of instances (34 per cent), the distribution of each coronary vessel is largely confined to the corresponding ventricle, thus, the right ventricle and the posterior part of the interventricular septum is supplied by the right vessel while the left ventricle and the anterior part of the septum is supplied by the left. In 18 per cent of the 225 hearts examined by Schlesinger, the distribution of the *left coronary* artery predominated. It supplied the whole of the left ventricle and a variable portion of the right chamber and of the septum.

Schlesinger has analyzed his anatomical findings and correlated them with the incidence of coronary disease. His results suggest that the second group, in which the blood supply to the heart is not predominantly through either the right or the left vessel, is the least vulnerable

to arteriosclerotic changes and their effects. The group in which the distribution of the left vessel predominates, appears to be the most susceptible while that in which the right vessel supplies the greater part of the heart stands in an intermediate position with regard to the incidence of coronary disease.

The heart muscle possesses an extraordinarily rich capillary supply. In the rabbit's heart the combined capillary length per cm. of tissue is about 11 meters as compared with 6 meters for active skeletal muscle. At birth a single capillary supplies 4 or 5 cardiac fibers. During growth the muscle fibers increase in size but not in number and each fiber in the adult heart receives a capillary vessel (Wearn), the number of vessels per unit of tissue remaining unchanged from that at birth. In cardiac hypertrophy, on the contrary, the enlargement of the individual fibers is not accompanied by a corresponding increase in vascularity of the muscle. The hypertrophied heart, therefore, suffers a relative reduction in its blood supply.

ANASTOMOSES

The coronary arteries form three types of anastomoses or communications:

(1) Anastomoses between branches of one coronary with those of the other. In the normal heart, the coronary branches are essentially "end arteries" (see p. 275), that is, no pervious channels of importance exist between them.

(2) Communications with the cavities of the heart:

(a) The THEBESIAN VESSELS, described by Vieussens in 1706 and by Thebesius in 1708, are small venous channels which open into the auricular and ventricular cavities. Thebesius demonstrated the communication of these vessels with the coronary system by inserting a blow pipe into a coronary artery and blowing through it after immersing the heart in fluid; bubbles were observed issuing from the heart cavities. The relations of these channels have been studied within recent years in the human heart by Wearn and by Grant and Viko in the heart of the sheep. They have been shown to communicate on the one hand with the cavities of both ventricles, on the other with the coronary sinus and other large coronary veins, and hence with the capillary bed of the ventricular muscle.

(b) DIRECT COMMUNICATIONS BETWEEN THE CORONARY ARTERIES AND THE VENTRICULAR CAVITIES, I.E., COMMUNICATIONS OTHER THAN

THROUGH THE CAPILLARY BED. These channels have been clearly demonstrated by Wearn and his associates in human hearts and are of two types which they term *arterio-luminal* and *arterio-sinusoidal* respectively. The arterio-luminal vessels are coronary branches from 0.2 to 1.0 mm. in diameter. They run a fairly direct course and usually retain their arterial characters up to the point where they open into the lumen of the heart. The arterio-sinusoidal vessels are branches of a coronary artery which break up into a number of irregular channels varying from 50 to 250 micra in diameter. These latter are called *myocardial sinusoids*. The walls of the sinusoids are composed of a single layer of endothelial cells, run a meandering course, and anastomose very freely with one another. The arterio-sinusoidal vessels thus provide, through the myocardial sinusoids, a means of free communication between the ventricular cavities and the coronary arteries.

(3) EXTRACARDIAC ANASTOMOSES. Potential communications between auricular twigs of the coronary arteries on the one hand, and branches of the internal mammary and aorta—pericardial, bronchial, phrenic and esophageal—on the other, have been demonstrated by Hudson, Moritz and Wearn. The site of anastomosis between these two systems is in the pericardial fat, and around the openings of the great vessels. These observers injected the coronaries from the aorta with a suspension of lamp black in acacia solution. A rich network of injected vessels appeared over the entire surface of the parietal pericardium (fig. 122), over the diaphragm and in the walls of the pulmonary vessels (*vasa vasorum*). The trachea, esophagus and mediastinum also showed injected vessels. Upon injection of the aorta, after tying it off distal to the orifices of the coronaries, and at the level of the diaphragm, the injected material was found in the coronary vessels around the openings of the pulmonary veins. Pericardial adhesions increase the extracardiac anastomoses.

Beck and Tichy, in a series of experiments upon dogs, have demonstrated the feasibility of developing the extracardiac anastomoses to such an extent that they can sustain the nourishment of the heart after almost complete occlusion (85%) of both coronary vessels. Adhesions were produced by incising the myocardium and stitching the pericardium into the wound; or by removing the epicardium and the endothelium of the pericardium. In other experiments an adjacent thoracic muscle, or the omentum drawn through an incision in the diaphragm, was utilized to establish communication between the coronary vessels and an

extracardiac vascular bed. Occlusion of the coronary arteries was brought about gradually by means of silver clips which were tightened in successive operations.² An operation devised on the basis of his experimental work has been performed by Beck upon patients suffering from angina pectoris due to coronary disease; the pectoralis major muscle was employed.

O'Shaughnessy has employed an omental graft (*cardio-omental cardiopexy*) with success in the treatment of angina. The omentum possesses the power of vascularization above all other tissues. The effectiveness of such a graft was clearly demonstrated in experiments upon grayhounds. Animals with the descending branch of the left coronary ligated and an omental graft were able to race over 500 yards.

Heinbecker and Barton injected an irritant mixture into the pericordial sac of dogs. Through the adhesions

FIG. 122. Drawing of the inner surface of the parietal pericardium and the inferior surface of the diaphragm. The coronary arteries were injected and the heart removed to expose the sites of anastomoses between coronary and extracardiac vessels. (After Hudson, Moritz and Wearn.)

set up effective collateral channels are said to have been established.

Interesting and encouraging as are these various procedures designed to increase extracardiac anastomosis, their value in angina pectoris has not been proved (see Marvin).

It does not appear that anastomotic communications play any significant rôle in supplying blood to the normal heart. When a large coronary branch is suddenly occluded, the back-flow in the section of the vessel distal to the occlusion is only about 1 cc. per minute and the myocardium normally supplied by the obstructed vessel ceases to contract within from 1 to 2 minutes. Nor

²Occlusion of the coronary sinus in animals is also claimed to encourage the development of collateral channels and to reduce the mortality following ligation of a large coronary branch.

does occlusion of other coronaries reduce the back-flow in the distal section of the previously occluded vessel. On the other hand, gradual occlusion of a coronary is followed by the development of a back-flow from other coronary branches as a result of altered pressure gradients. The pressure in the peripheral section of the occluded vessel increases and may approach the aortic pressure. In the dog, the retrograde flow usually amounts to from 30–40 cc. per minute and, in some

FIG. 122A. Comparison of the curves representing intramural and total inflow at a coronary orifice in the left coronary (A) and in the right coronary (B) together with the pressure curves from which the intramural flow was reconstructed. instances, is over 100 cc. per minute. The myocardium, to which the occluded vessel is distributed, shows normal contractions (Gregg and associates). The importance of anastomatic channels in the supplying of the heart muscle in coronary disease is indicated by the observations of Wearn; he has reported cases in which post-mortem examination revealed the main coronary arteries to be completely occluded; yet the coronary occlusion had not been the cause of death,

but must have been of long standing. The heart muscle, apparently, had in these instances been nourished through channels communicating with the ventricles or through extra-cardiac anastomoses, or through both of these routes. According to Gross, anastomoses between the branches of the coronaries multiply with age and the vascularity of the muscle, especially of the left ventricle and septum, increases.

The possible functional significance of the communications between the coronary system and the ventricular cavity is indicated by the experiments performed some years ago by Pratt. He was able to keep the *isolated* heart of the cat beating for an hour by perfusing it through a cannula tied into the ventricle. Katz and his colleagues introduced a pure culture of killed bacteria into the superior vena cava of a heart-lung preparation (precautions having been taken that bacteria did not enter the coronary system from the arterial side). The bacteria were found later in the sinusoidal spaces, capillaries and the small arteries of the myocardium. These authors conclude that though the quantity of blood conveyed from the ventricles to the *normal* heart muscle is small, in some pathological states associated with narrowing or occlusion of coronary vessels, it may be sufficient to aid significantly in nourishing the myocardium. The results of Stella's experiments on the heart-lung preparation of the dog also indicate that in a heart whose muscle is supplied with blood through the coronary system, back-flow does not occur to any important extent from the ventricles into the coronary vessels. Even when the ventricular pressure was higher than the coronary pressure no evidence of back-flow was secured.

CORONARY CIRCULATION TIME AND VOLUME FLOW

The coronary circulation is one of the shortest in the body. The blood passes through arterioles into a capillary bed and is collected by veins which empty through the coronary sinus into the right auricle. Evans and Starling calculated that 60 per cent of the blood of the coronary circulation is delivered into the right auricle by the coronary sinus. The remaining 40 per cent must find an outlet through other channels—the Thebesian and other communications mentioned above.⁹ According to Wearn, the proportion of blood re-

turned otherwise than through the coronary sinus may, under certain conditions, be much greater than 40 per cent. The blood vessels of the left ventricle drain mainly through the coronary sinus, whereas the Thebesian vessels and other luminal vessels drain the right ventricle. A rise of pressure in the pulmonary circulation (and therefore of the pressure in the right ventricle) reduces the pressure gradient between the coronary arteries and the Thebesian vessels and causes thereby, slowing of the flow along these channels. Such slowing interferes very seriously with the nutrition of the right ventricular muscle. Moe and Visscher found that a reduction in the aortic-pulmonary pressure difference to 40 mm. Hg, either by a fall in aortic pressure or a rise in pulmonary pressure, diminished the Thebesian flow to 20 per cent of the normal. The dependence of the nutrition of the right ventricle upon the venous return through the Thebesian vessels is probably the reason that this side of the heart can work for a relatively short time against a high pulmonary resistance (e.g. mitral stenosis or pulmonary fibrosis) whereas the left ventricle is able to work for years against a high aortic pressure, since the flow from the coronary sinus is not affected by the high pressure in the left ventricle. A rise in aortic pressure by increasing the pressure gradient might therefore be expected to benefit cases of cardiac disease with raised pulmonary pressure. Such benefit has been observed.

The coronary circulation time, that is, the time taken for a red cell (following the shortest route) to pass through the coronary system is about 8 seconds as compared with 20 seconds through the vessels of the limbs.

Experiments upon animals (heart-lung preparation) indicate that about 5 per cent of the total output of the heart flows through the coronary system. The output of the human heart under basal conditions is between 3 and 4.6 liters per minute, but during strenuous muscular exercise it may, in the case of a large muscular subject, rise to 37 liters. In such an instance, if the volume of the coronary flow were 5 per cent of the total blood flow, nearly two liters would pass through the coronary system. The coronary flow in man can be estimated in another way. The work of the heart, for example, can be calculated approximately from the cardiac output and the mean arterial blood pressure (p. 115). Taking the efficiency of the heart at 20 per cent, the oxygen consumed by the myocardium can

⁹The latter is probably only a very approximate figure which varies considerably under different conditions, such as, especially, the pressure in the right ventricle.

be calculated from the work performed. The results of such calculations indicate that the heart muscle during strenuous exertion consumes as much oxygen as does the entire body during rest (Hill), or about 250 cc. per minute. Assuming that during maximum muscular effort the coefficient of oxygen utilization is 0.7 (p. 322), that is to say, the heart muscle removes about 13 cc. of oxygen from each 100 cc. of blood, (arterio-venous oxygen difference = 13 vols.) then the delivery of 250 cc. of oxygen requires a flow of $\left(\frac{250}{13} \times 100 = \right)$ about 2 liters of blood through the coronary system per minute, or an amount of blood having a weight more than 6 times greater than that of the heart itself (300 gm.). The coefficient of oxygen utilization of the heart muscle is probably, in most instances, lower than the figure given; the blood flow would then be greater for an equivalent oxygen consumption. The A-V oxygen difference of the coronary blood of the dog at rest is from 8 to 16 volumes.

THE CORONARY FLOW DURING DIFFERENT PHASES OF THE CARDIAC CYCLE

Scaramucci, an Italian of the 17th century, was the first to recognize that unlike other arteries the flow through the coronary arteries occurred mainly during diastole, and that a reduced amount of blood entered the vessels during systole owing to their compression by the contracting cardiac muscle. Stroem offered an anatomical reason for the reduced flow during systole, namely, that the leaves of the aortic valves blocked the coronary orifices during this phase of the cycle. This explanation was soon shown to be incorrect, for the edges of the open valves in many cases do not reach as far as the coronary orifices. Langendorff studied the problem intensively in the perfused isolated heart, and our knowledge of the coronary flow during the cardiac cycle is based largely upon his work. In more recent times, Anrep and his colleagues in England, and Wiggers, Green and Gregg with their associates in America have been the outstanding contributors in this field.

The coronary inflow. The flow in the coronary system is affected profoundly by the compressing force of the cardiac muscle during systole. The flow through the peripheral vessels, which are surrounded by muscle and are directly compressed, is referred to as the *intramural flow*. The flow through the larger more superficial coronary

branches, is called the *extramural flow*; and is affected both directly and indirectly by compression during systole. The total flow (intra and extramural) in a coronary vessel can be determined by perfusing the vessel through its orifice and measuring, by some form of flow meter, the quantity of fluid which enters. But such a method has the disadvantage that the coronary circulation is not maintained under natural conditions, that is, with a normal pulsatile aortic pressure. Wiggers and his associates find, however, that the pressure in the peripheral coronary vessels never rises as high as the aortic pressure, that is, the pressure gradient is not abolished at any time during the cardiac cycle. The intramural flow, therefore, is not completely arrested. But, two sharp reductions in the flow occur, one in the isometric period and at the beginning of ejection, the other in the latter part of the ejection period. The rate of flow is greatest in mid-systole and throughout diastole.

The curve of total coronary flow (intra and extramural) as measured at a coronary orifice, resembles that of the intramural flow, except that the total flow is *completely* arrested during early systole and is greater during mid-systole and the first half of diastole. The arrest of the total orifice flow in early systole is attributed to compression of the deeply placed vessels which forces blood backwards into the larger superficial vessels and thus opposes the flow from the aorta at this time. But the pressure in the peripheral vessels never rises as high as the aortic pressure, so that the onward flow in these vessels is never completely stopped. As the aortic pressure rises during systole, the superficial vessels are distended and the extramural flow increases over that in the deeper-lying and compressed intramural vessels. During early diastole, the peripheral vessels are quickly released from compression and the flow through the extramural vessels, no longer impeded by back-flow, is augmented.

The contours of the blood flow curves of the *right coronary* differ from those of the left vessel in that the reduction in the rate of flow in early systole is not nearly so pronounced and the rate of total orifice flow does not exceed the intramural flow to as great a degree (fig. 122A). The flow during systole may approach or even exceed that during diastole.

The thermo-stromuhr of Rein (p. 145), as modified by Baldes and Herrick, has been employed by Essex

and associates for measuring the coronary flow in conscious animals (dogs). The chest was opened and the instrument placed in position. The connecting wires were then led to the exterior and the chest closed. After recovery from the operation, blood flow determinations were made from time to time under various physiological conditions. The flow was found to be increased during digestion by over 80 per cent and by about 400 per cent when the animal performed strenuous work.

Coronary Pressures

The pressure curve of a coronary artery has a form closely resembling the aortic pressure curve. The minor differences which are to be seen in the pressure pulse of a coronary artery are not peculiar

FIG. 123. The relation of coronary outflow to other events in the cardiac cycle. (After Anrep and associates.)

to that vessel but appear in pulses recorded from other branches of the aorta. The pressure in the right coronary artery is lower than in the left coronary but is considerably higher than the pressure in the right ventricle, whereas the pressure in the left coronary is lower than the left ventricular pressure. The pressure in the coronary sinus amounts to 10 or 12 mm. Hg.

The outflow from the coronary sinus. The flow from the coronary sinus is increased slightly during the latter half of auricular systole and very greatly during ventricular ejection. A graphic record of the outflow, therefore, shows two well-defined waves (cf. fig. 123). The first and smaller wave is probably due to the compression of the walls of the coronary sinus by the auricular muscle and the expulsion of a small quantity of blood. Evidence for the dependence of this wave upon

auricular contraction is, that it occurs during the latter part of the P deflection of the electrocardiogram, that it disappears during auricular fibrillation, and that in heart block it synchronizes with the auricular contractions.

The large wave occurring during the ejection phase of ventricular systole is due to the blood being squeezed from the coronary veins by the grip of the ventricular muscle. At the end of ventricular systole the outflow falls suddenly as a result of the release of the veins from the compressing force of the muscle. The vessels having been practically emptied must refill before the flow from the coronary sinus is resumed.

A diminutive wave is seen in the figure between the two waves just described. It occurs during the isometric period of ventricular systole but its cause is uncertain.

FACTORS REGULATING THE CORONARY CIRCULATION

(1) *THE AORTIC BLOOD PRESSURE.* The height of the mean aortic pressure, and especially of the mean pressure in the aorta following the closure of the semilunar valves (postdiastolic pressure), and the resistance in the peripheral coronary vessels are the most important factors determining the coronary inflow. For example, in aortic regurgitation, or arterio-venous aneurysm produced experimentally, the coronary flow is decreased due to the sharp fall in diastolic pressure, but in these conditions during systole, the aortic pressure is elevated to a greater degree than the peripheral coronary pressure. The steeper pressure gradient results in a greater systolic flow which compensates, in part, for the decreased flow during diastole. In experimental aortic stenosis systole is prolonged and the coronary flow correspondingly reduced; the flow during diastole is not significantly affected.

(2) *INNERVATION OF THE CORONARIES.* Woolard has demonstrated by histological studies that the coronary vessels are richly supplied with both vagal and sympathetic fibers. The larger branches were found to be innervated about equally by the two types of nerve, whereas the arteriolar innervation was mainly through the vagus. The action which each of these two sets of fiber exerts upon the heart has, however, been a moot question for several years and a very difficult one for investigation, since stimulation of the vagus, or of the sympathetic, causes changes in the action of the heart which in turn influence the coronary circulation.

Though the question of the actions of the vagus and sympathetic nerves upon the coronaries has not received a final answer, the weight of evidence indicates that, in the mammal, the vagus is vasoconstrictor, while the sympathetic and adrenaline are vasodilator. Anrep and Stacey observed an increase in coronary flow of 85 per cent after the administration of adrenaline, and several workers have reported an increased flow from stimulation of the stellate ganglia. Mann and associates, employing the thermo-stromuhr, observed an increase of 300 per cent in the coronary flow after the administration of adrenaline or ephedrine. Wiggers showed that stimulation of the peripheral end of the cut vagus in an animal under the influence of atropine, which in suitable dosage abolishes the vagal action upon the heart but not upon the coronaries, reduced the flow from a coronary vein. Diminution in coronary flow upon vagal stimulation was also demonstrated by Anrep and Segall, using the heart-lung preparation and the hot wire method of recording. The effect persisted though constancy of heart rate was secured by atropinization. Anrep and Segall also found that the coronary flow was increased considerably after vagal section, a fact which indicates that these nerves exert a tonic vasoconstrictor influence. The vagus, as we know, exerts its effect through the liberation of acetylcholine, and this substance has been demonstrated by Feldberg and Kraye in the coronary blood during vagal stimulation. One would therefore expect acetylcholine to reduce the coronary blood flow. On the contrary, this chemical dilates the coronaries in mammals, an effect which is not abolished by atropine; it has a pronounced constrictor action, however, upon the coronaries of birds (see also Gregg).

The coronary dilatation and consequent increase in flow which follow sympathetic stimulation or adrenaline administration are what one should be led to expect from the known emergency function of the sympatho-adrenal mechanism. Through the action of this mechanism the efficiency of the body in the performance of work or in combating the dangers of the environment is raised to a high level; the mean arterial blood pressure is elevated as a result of vasoconstriction in the skin and splanchnic areas while the vessels of the contracting skeletal muscles and brain are dilated; the force of the cardiac contraction is augmented. It would be odd if such effects, directed toward the general improvement of the circulation during muscular effort, were antago-

nized by a coincident constriction of the coronary arteries. But perhaps the question of the sympathetic action upon the coronaries is really of no great practical importance since the response of the coronaries in dogs after sympathetic denervation is just as great as in normal animals; nor is the dilator effect following stimulation of the stellate ganglion pronounced. The coronary vessels are also supplied with afferent fibers from both the vagus and the sympathetic. Coronary reflexes initiated from the abdominal and thoracic viscera have been demonstrated. Thus, stimulation of the abdominal organs in animals has been shown to cause coronary constriction. A coronary dilator reflex is initiated by a rise of pressure in the right auricle or vena cava.

FIG. 124. Curves showing the relation of the coronary blood flow and of the oxygen consumption by the heart to the oxygen saturation of the blood passing through the coronary vessels. (Hilton and Eichholtz.)

(3) ALTERATIONS IN THE OUTPUT OF THE HEART.

Increase in the venous inflow, and so in the minute volume of the heart, the mean aortic pressure being kept constant, markedly augments the flow through the coronary system if the vagus nerves are intact. On the contrary, a rise in the cardiac output with a constant aortic pressure, exerts a negligible influence upon the coronary circulation after the vagus nerves have been cut. The calibers of the coronary vessels are evidently widened as a result of a reflex inhibition of the constrictor tone of the vagus. This response, which is known as the *coronary reflex*, is not abolished by excision of the stellate ganglia.

(4) OXYGEN LACK AND CARBON DIOXIDE EXCESS. Anoxia increases the coronary flow very greatly. Reduction in the oxygen saturation of the arterial blood below 20 per cent was shown by Hilton and Eichholtz to cause maximal dilatation of the coronary vessels and a five-fold increase in flow (fig. 124). The addition of cyanide to the coronary blood exerted a similar effect. Carbon dioxide and lactic acid in the absence of a

reduced oxygen supply caused only a very moderate dilatation of the coronary vessels. Reactive hyperemia (p. 271) is a very pronounced phenomenon of the coronary circulation (Katz and Lindner).

(5) **VARIATIONS IN HEART RATE.** It is to be expected that, since the coronary arteries fill during diastole and are compressed during systole, an increase in heart rate, which causes shortening of diastole relatively to systole, will decrease the coronary flow. A diminution in coronary flow does occur when the rate of beating is so great that the total time occupied each minute by the diastolic periods (minute-diastole) is much reduced. When the rate is very slow, other factors remaining constant, the flow is augmented. Within the physiological range, however, a change in heart rate (70 to 180) appears, in itself, to have little effect upon the coronary flow.

(6) **DRUGS.** Nitrites, cyanides, caffeine, camphor, adenosine and mecholyl increase the coronary flow. The action of histamine varies in different species; the drug exerting a constrictor action upon the coronaries in the rabbit but a dilator effect upon those of the cat. By means of the thermostromuhr Essex and his colleagues have investigated the action of a number of drugs on the coronary flow in unanesthetized dogs. Histamine, coramine (pyridine- β -carboxydiethylamide), atropine and nembutal were found to increase the flow from 60 to 100 per cent; pituitrin decreased it by as much as 80 per cent. Thyroxine increased the flow by 250 per cent. The effects of adrenaline and acetylcholine upon the coronary blood flow have been mentioned. Alcohol, according to Sulzer, when it reaches a concentration in the blood of 0.1 per cent or more causes constriction of the coronary vessels and a reduction of the coronary flow. Drugs which increase the coronary flow in normal hearts have apparently little or no effect in increasing the blood supply to an infarcted area.

DISEASE OF THE CORONARY ARTERIES

The coronary arteries are very frequently the site of degenerative changes—atheroma and sclerosis—especially after the fifth decade of life. These changes, when advanced, lead to narrowing of the arterial lumina and a gradual insufficiency of the blood supply to the heart muscle. Milder grades of coronary disease are usually unaccompanied by symptoms or any clinical signs. Two conditions, namely, *angina pectoris* and *acute coronary occlusion*, are commonly associated with the more severe grades of coronary sclerosis. Auriculo-ventricular, or bundle branch block, *pulsus alternans* (Chapter XXIV) and low voltage electrocardiograms are other consequences of coronary disease.

Angina pectoris—angina of effort

These terms are given to paroxysms of severe and often agonizing cardiac pain which occur usually as a result of exertion, and last for a few seconds or minutes. The pain is felt most usually beneath the upper or middle third of the sternum; it is frequently referred to the neck, left shoulder or arm. During the attack, electrocardiographic changes frequently appear similar to those seen in coronary thrombosis (p. 281).

Anginal attacks are most commonly precipitated by effort or some form of emotional excitement, under which circumstances the minute volume of the heart is increased but the blood supply to the myocardium is inadequate for the extra work demanded of it. An increase in the cardiac output has been demonstrated in anginal attacks. The increased work of the heart during digestion also in all likelihood accounts for the common occurrence of angina following a heavy meal. Effort at this time is particularly likely to precipitate an attack in a susceptible subject.

Several views have been expressed concerning the cause of anginal pain, e.g., spasm of the cardiac muscle, sudden stretching of the wall of the aortic arch or contraction of the coronary arteries. There is, however, no change in the rhythm of the heart which would indicate the existence of spasm; distension of the aorta in animals by means of a dilator introduced through the carotid does not give rise to pain, and since the coronary vessels are so often hard and stiff spasmodic constriction of their lumina seems out of the question. The pain is evidently directly related to anoxia of the heart muscle—the oxygen supply being inadequate for the work which the heart is called upon to do.

Angina, for example, may occur though the coronary vessels are normal if the oxygen supply to the tissues is deficient, as in anemia or in rarefied atmospheres; and in aortic regurgitation the coronary circulation may be so diminished as a result of the low diastolic pressure (p. 278) that anginal attacks occur though the heart vessels themselves are fairly healthy. Also in hyperthyroidism, when the burden thrown upon the heart is already greatly in excess of the normal, the extra cardiac work occasioned by exertion may so tax a normal coronary system to furnish an adequate blood supply to the heart muscle, that cardiac pain results. In severe anemia, the low oxygen-carrying capacity of the blood is compensated during rest by an increase in the circulation

rate; the coronary flow is then adequate, the heart is able to perform the extra work entailed and the tissues do not suffer from oxygen lack (p. 356). Upon exertion, however, the heart is called upon to increase its output further in order to furnish the required amount of oxygen to the contracting muscles. But the urgent demands of the heart muscle itself for extra oxygen cannot be met, since the coronary flow is already near its maximum—anoxia of the myocardium and of the tissues in general results. In cardiac hypertrophy and dilatation, anginal attacks may also occur, though the coronaries are not diseased, and is then apparently the result of the small coronary flow *relatively* to the size of the heart (p. 274). When congestive failure supervenes the greater oxygen requirement of the inefficient myocardium (p. 218) is an additional factor.

Additional support for the view that anoxia is the prime factor in precipitating an anginal seizure is afforded by the observations of Katz and his colleagues. General anoxia induced in subjects of the disease by having them breathe an oxygen-poor atmosphere was accompanied by the appearance of characteristic electrocardiographic features (reduced amplitude or inversion of the T wave and depression of the S-T segment); a third of the subjects experienced typical anginal pain. Anoxia produced in the same way in normal subjects caused similar features to appear in the electrocardiogram, though pain was not experienced.

The pain of angina pectoris is believed to be produced in a manner essentially the same as that in which the pain of intermittent claudication is produced, namely, through the stimulation of afferent nerve endings in the myocardium by metabolic products accumulated as a result of oxygen deficiency (p. 257).

The anginal attack is treated by means of nitrites (amyl nitrite, nitroglycerine, sodium nitrite) which by causing peripheral vasodilatation reduce the work of the heart and through their dilator effect upon the coronary vessels tend to increase the blood supply to the cardiac muscle. Amyl nitrite which is administered by inhalation acts almost instantaneously but its action is evanescent; it is therefore employed to arrest an attack. The other nitrites act more slowly but their effects are more lasting; they are used in the intervals between attacks. Adenosine compounds (p. 253) are also sometimes employed for their vasodilator effects. Complete thyroidectomy, which by lowering the metabolic rate reduces the cardiac work, has been advocated in certain selected cases (p. 226).

The impulses giving rise to cardiac pain pass from the heart to the central nervous system mainly via the inferior cardiac nerve, the upper four or five thoracic ganglia and the corresponding white rami and posterior nerve roots (see referred pain, p. 514). Pain is not, apparently, transmitted through the vagus. Sutton and Lueth found that in conscious dogs, traction upon a ligature passed loosely around a coronary artery and brought out through the thoracic wall was followed by nausea, vomiting and evidence of pain. The response was abolished after removal of the stellate ganglia but persisted after section of the vagi.

Removal of the left stellate ganglion or the injection of alcohol around the upper five left thoracic ganglia (paravertebral injection) is sometimes resorted to for the relief of anginal pain. The afferent nervous pathways are thus interrupted and the patient is relieved of his attacks. No change in the underlying condition responsible for the pain is brought about by these measures, and since pain is a signal which warns the patient against heart strain, its abolition is not an unmixed blessing.

Acute coronary occlusion. Coronary thrombosis. Cardiac infarction

Smith in 1918 studied the effects of ligation of various branches of the coronary vessels in dogs. Of 11 animals in which the anterior descending branch of the left coronary was ligated 10 survived. The left circumflex artery was ligated in 14 animals; 6 survived. Ligation of the right coronary close to its origin was performed in 8 animals, only one of which recovered from the operation. In 18 animals the anterior descending branch of the left coronary and one or more branches of the left circumflex artery were tied; only 4 animals recovered from this operation; 9 died within 24 hours, 3 others died from infection and 2 from failing heart on the 15th and 17th days respectively.

Clinically, thrombosis is the commonest cause of acute coronary occlusion, though occasionally a vessel is blocked by an embolus. Obstruction of a main branch of a coronary artery is accompanied usually by severe pain, similar in character to that described under angina pectoris; dyspnea; nausea and vomiting; and often the signs of profound collapse. Other features of the attack are low blood pressure, fever, and leucocytosis. A fatal termination (due probably in many instances to ventricular fibrillation) either during

the attack or a short time later is common. The nausea and vomiting together with the fact that the attack not infrequently followed a heavy meal or a drinking bout has led in the past to many cases of coronary thrombosis being diagnosed as "acute indigestion." The underlying cause of coronary thrombosis is usually atheroma or

supplied by the occluded vessel softens, undergoes necrosis and is finally replaced by a scar; or the heart may rupture through the infarcted area, death then resulting from hemorrhage. Cardiac hypertrophy may be a delayed effect of coronary occlusion (p. 220). Minor coronary branches may become obstructed without giving rise to any

FIG. 125. Electrocardiogram in acute coronary occlusion. *a*, T_1 , type of tracing; *b*, T_2 , type; *c*, same patient as (*a*) 16 days later. (Kindness of Dr. John Hepburn.)

FIG. 126. Low voltage electrocardiogram, lead III. (Kindness of Dr. John Hepburn.)

sclerosis of the arterial wall and a gradual constriction of its lumen. The majority of subjects have suffered previously from anginal attacks. The anterior descending branch of the left coronary is most frequently thrombosed and for this reason has been called the *artery of sudden death*.

If death does not result from the immediate effects of the attack the area of myocardium

symptoms, the myocardial area involved being nourished through collateral vessels; or, should the occlusion of even a large branch occur gradually, collateral channels become established which are sufficient to maintain the vitality of the area of distribution of the obliterated vessel (p. 274).

The electrocardiogram immediately following an attack of coronary thrombosis often shows characteristic features which were first pointed out by Pardee. Similar features were described by Smith following coronary ligation in dogs. In occlusion of the anterior descending branch of the left coronary, the most usual electrocardiographic changes are as follows. The descending limb of the R deflection in lead I does not reach the base line but gives rise in its lower third to the T wave, i.e., the R-T interval lies well above the base line (see fig. 125*a*). In lead III, on the other hand, the descending limb of R passes below the base line but does not rise sharply again before

giving rise to the T wave; the S-T interval is therefore depressed. In occlusion of the right coronary it is usual to find these characteristic features in the two leads reversed, the S-T interval being depressed in lead I and the R-T interval elevated in lead III (fig. 125*b*). The electrocardiogram changes in character as recovery progresses, gradually returning to normal though an inverted T wave in lead I (left coronary occlusion) or in lead III (right coronary occlusion) often persists. The electrocardiogram resulting from left coronary occlusion is therefore frequently referred to as the T_1 type of record (fig. 125*c*); that associated with occlusion of the right artery as the T_3 type. (Parkinson and Bedford)

Probably the most characteristic electrocardiographic feature of coronary occlusion is the variability of the tracing from day to day during the period following the attack.

LOW VOLTAGE ELECTROCARDIOGRAMS. These are seen most frequently in subjects of myocardial degeneration resulting from coronary disease (fig. 126). The range of voltages for the normal electrocardiogram is given on page 181. Low voltages are also seen in a certain proportion of cases of hypothyroidism and in massive pericardial effusions. Electrocardiograms showing these low voltages, except in the last two mentioned instances, are of grave prognostic significance. In 68 per cent of a series of cases observed by Hepburn and Jamieson the average duration of life after this electrocardiographic feature had been first observed was 6 months.

THE PULMONARY (LESSER) CIRCULATION⁴

The blood is conveyed from the right to the left side of the heart through the pulmonary circuit, and the quantity passing per minute obviously must equal the quantity flowing in the same time through the rest of the body, namely, from 3 to 4.6 liters under basal conditions. The pulmonary vessels like those of the systemic system consist of arteries, arterioles, capillaries and veins; the pulmonary arteries break up abruptly into short, wide branches. The minute vessels of the lung, unlike those of any other vascular area, are almost surrounded by air. Though each capillary is only from half to one millimeter in length and of the order of 10 microns in diameter, the total capillary surface exposed to the lung air has been estimated at about 140 square meters (Hufner).

The vessels of the lung are highly distensible and their capacity alters with (a) changes in intra-thoracic pressure incident to the respiratory movements, and (b) alterations in the minute volume of the right ventricle in relation to the resistance on the left side of the heart.

The velocity of flow through the individual pulmonary vessels varies directly with the output of the right ventricle and inversely with the capacity of the vascular bed. That is, the capacity of the vessels remaining constant, an increase in the output of the right ventricle increases the velocity of flow in the minute vessels (p. 148) and vice versa. An increase or decrease in the capacity of the vessels and thus in the total sectional area of the vascular bed, the right ventricular output remaining unchanged, slows or quickens, respectively, the blood flow through the pulmonary circuit.

The mean arterial pressure in the pulmonary circuit has a value approximately a sixth of that in the aorta—about 25 mm. Hg in the dog and probably from 18 to 20 mm. in man. A systolic pressure of around 40 mm. Hg and a diastolic pressure of about 10 mm. Hg have been recorded in the dog, i.e., a rise in pressure of 30 mm. Hg occurs with each heart beat. In contrast to the systemic circulation the pulmonary circuit has, therefore, a pulse pressure of higher value than the mean pressure. In the dog, the velocity of flow in the pulmonary artery is around 0.4 meters per second. The pressure in the pulmonary veins is ordinarily near the zero level—from -3 mm. H_2O in inspiration, to +4 mm. H_2O during expiration. The tone of the pulmonary arterioles is relatively low, so that a rise in the pulmonary venous pressure is readily transmitted to the arterial side. As a result of the high degree of distensibility of the pulmonary vascular bed, due mainly to the opening up of fresh capillaries, the blood contained within the lungs shows wide variations under different conditions. Unless extreme, variations in the quantity of blood in the lungs are accompanied by little or no change in pressure. Ordinarily the lungs hold about 9 per cent of the total blood volume during inspiration and 6 per cent during expiration; under certain circumstances the quantity of blood in the pulmonary vessels may increase to 20 per cent or more of the total blood volume. Increased resistance to the flow of blood in the pulmonary veins, as in mitral stenosis or as a result of failure of the left ventricle (p. 222), raises the pressure in the pulmonary system. Engorgement of the

⁴The bronchi and bronchial lymph nodes, the interstitial tissue of the lungs and the walls of the larger arteries are supplied by systemic vessels, small branches of the aorta p. 294.

lung vessels results, the distended capillaries encroach upon the air spaces and the vital capacity, in consequence, is reduced. Also, increased filling of the right heart during muscular exercise results in a greater systolic discharge from the right ventricle into the pulmonary circuit. The left ventricle does not respond instantly to the greater inflow, but only after a beat or two, or until the pulmonary venous pressure rises sufficiently to distend the ventricular cavity and stretch the muscle fibers (p. 216). The ventricle then discharges as much blood as it receives. The rise in venous pressure has, however, resulted in distension of the pulmonary vessels and an increase in the total quantity of blood contained in the lungs. This ready distensibility of the vascular bed of the lungs accounts for the fact that little or no rise in pulmonary arterial pressure occurs during muscular exercise, despite the great increase in cardiac output. Nor is the pulmonary blood pressure elevated in experimental renal hypertension.

The blood flow from the venae cavae into the heart remaining constant, a rise in aortic pressure is attended by a rise in pulmonary arterial pressure. This is not a "back-pressure" effect due to the left ventricle failing to discharge its contents adequately against the raised systemic resistance, but is the result, as shown by Anrep and Bulatao, of the greater quantity of blood returned to the right ventricle through the coronary system and, in consequence, of the larger quantity discharged into the pulmonary circuit.

THE EFFECTS OF THE RESPIRATIONS UPON THE PULMONARY AND SYSTEMIC BLOOD PRESSURES

The pulmonary arterial pressure falls during ordinary inspiration and rises during expiration. One should expect that, as a result of the increased flow of blood into the right ventricle during inspiration, and the greater systolic discharge, the pulmonary pressure would *rise* during this phase of respiration. Due, however, to the traction exerted upon the circumference of the pulmonary vessels by the surrounding lung tissue, their capacity is increased. This more than compensates for the greater amount of blood entering the pulmonary circuit during the inspiratory phase. During expiration these effects are reversed. The right systolic discharge is less but the capacity of the vascular bed of the lungs is at the same time reduced; an upward swing in pulmonary arterial pressure occurs. With

maximal expansion of the lungs or during a forced expiration with the glottis closed (Valsalva's experiment, p. 138) the vessels are strongly compressed by the surrounding lung tissue and the pulmonary arterial pressure rises sharply.

The increased capacity of the pulmonary vessels during inspiration reduces, momentarily, the flow of blood into the left auricle; the consequent reduction in the systolic discharge of the left ventricle causes a fall in aortic pressure. After a few beats of the right ventricle the greater capacity of the pulmonary vessels again becomes filled and the flow of blood into the left chambers of the heart increases; the aortic pressure rises. The succeeding expiration by reducing the capacity of the pulmonary vessels drives blood to the left side and further increases the discharge into the

FIG. 127. Curve of arterial blood pressure, showing the effect upon it of the respirations. For the sake of simplicity the smaller waves due to the heart beat, and normally seen superimposed upon the respiratory waves, have been omitted.

aorta; the systemic pressure, in consequence, continues its rise until near the end of the expiratory phase. The large undulations which appear in the blood pressure tracings of animals are due to these effects. If the respiratory movements and the systemic blood pressure are recorded simultaneously it is found that the blood pressure commences to fall at the commencement of inspiration and reaches its lowest point in the latter half of this phase, the blood pressure tracing then commences to rise and reaches its maximum toward the latter part of expiration⁵ (fig. 127).

NERVOUS REGULATION OF THE PULMONARY VESSELS

The pulmonary vessels receive vasoconstrictor fibers through the *sympathetic*. The first definite evidence of a vasoconstrictor supply to the vessels of the lung was secured by Bradford and Dean who stimulated the peripheral ends of the thoracic nerves from T2 to T7 in the dog and observed a rise in pulmonary arterial pressure without any

⁵ See Heinbecker.

change in heart rate or in systemic blood pressure. Daly and Euler have obtained evidence that the sympathetic of the dog also contains vasodilator fibers. Adrenaline causes constriction of the pulmonary vessels, except in high dilution when it causes vasodilatation.

The *vagus* of the dog carries both vasoconstrictor and vasodilator impulses to the lung. The distribution of the vasoconstrictor and vasodilator fibers to the pulmonary vessels varies considerably, however, in different species. Though in the dog, as just stated, both the sympathetic and the *vagus* contain vasoconstrictor as well as vasodilator fibers, sympathetic stimulation gives predominantly vasoconstrictor⁶ and vagal excitation vasodilator effects. In the rabbit, on the other hand, only constriction of the pulmonary vessels can be obtained by stimulation of the *vagus*; this effect is abolished by atropine and enhanced by eserine. Further evidence of the vasodilator action of pulmonary parasympathetic fibers in the dog and of their vasoconstrictor action in the rabbit is provided by the action of acetylcholine; this parasympatho-mimetic drug causes dilatation of the pulmonary vessels of the dog, and constriction of those of the rabbit.

It is probable that the innervation of the pulmonary vessels is of little physiological importance. Indeed, the need of vasomotor control of the pulmonary circulation is not evident.

PULMONARY CARDIOVASCULAR REFLEXES

Evidence for the existence of proprioceptors in the vascular bed of the lungs has been furnished by the experiments of Schwegk and of Daly and associates. The latter perfused the pulmonary and the systemic vessels separately with oxygenated blood. Increased pressure in the pulmonary circuit caused a slight fall in systemic arterial pressure and an increase or a decrease in the heart rate. The fall in systemic blood pressure was more readily produced by raising the pressure in the pulmonary veins, as may follow obstructing the outflow from the left auricle. The effect is evidently purely reflex in character, for it is abolished by section of the vagosympathetic nerves. A reflex of this character may play some part in the fall of

⁶One is tempted to doubt that these experimental results reflect what actually occurs in normal unanesthetized animals, for the sympathetic which is called into play in preparing the body in emergencies would then act to impede the blood flow through the lungs. Furthermore, in muscular exercise a discharge of impulses over sympathetic paths occurs yet the pulmonary arterial pressure does not rise as it would be expected to do were pulmonary vessels constricted.

systemic blood pressure which occurs in left ventricular failure and in pulmonary embolism.

Inflation and deflation of the lungs within the physiological range causes, respectively, acceleration and slowing of the heart. This respiratory arrhythmia is often very pronounced in young persons (p. 204). The mode of its production has been studied experimentally by a number of investigators. According to Anrep, two mechanisms are concerned, reflex and central. The *reflex* effect is through afferent pulmonary terminals, the *vagus* center and efferent cardiac *vagus* fibers. The impulses set up by inflation cause depression of the tone of the *vagus* center (cardio-inhibitory) with consequent increase in heart rate. The reflex effect is abolished by sectioning either the pulmonary (afferent) or the cardiac (efferent) vagal fibers. The afferent impulses exert no influence upon the cardio-accelerator mechanism, for excision of the stellate and upper thoracic ganglia does not alter the response. The reflex is initiated apparently through the stretch receptors in the visceral pleura or in the layer of lung tissue immediately subadjacent to it. These receptors adapt rapidly and if the inflation is protracted secondary slowing of the heart occurs. Extreme inflation of the lungs causes cardiac slowing rather than acceleration. The slowing of the heart caused by deflation of the lungs is accompanied by depression of auriculo-ventricular conduction; in a heart in which there is already some delay, in conduction over the bundle, deflation may cause complete heart block. The *central* factor in the mechanism leading to cardiac acceleration following inflation is generally believed to be due to the radiation of impulses from the respiratory to the cardio-inhibitory center. It is not abolished by section of the pulmonary fibers of the *vagus* or paralysis of the respiratory movements by means of curare.

THE CIRCULATION THROUGH THE LIVER

The liver receives blood from two sources—from the gastro-intestinal tract, spleen and gall-bladder through the *portal vein*, and from the aorta through the *hepatic artery*.

The portal vein differs from other veins in that it divides into numerous branches which ultimately form a rich capillary network within the liver substance. In this it resembles an artery, but unlike an artery it is interposed between two capillary beds—one, as just mentioned, in the liver, the other in the splanchnic area which it drains. The primary branches of the portal vein upon entering the liver divide into vessels which run between the hepatic lobules (fig. 128). These—the *interlobular veins*—give rise to capillary-like vessels called the *hepatic sinusoids* lying between the liver cords and separated each from a bile capillary by a single layer of hepatic cells. The Kupffer cells (p. 80) are found within the sinusoids, attached by delicate strands to their walls. The sinusoids converge toward

the center of the lobule—like the spokes of a wheel toward its hub—where they empty into a wider channel running perpendicularly to them, and called the *central vein*. The central veins of neighboring lobules join in groups to form *sublobular veins* which unite in turn to form *hepatic veins*. After a series of unions and the formation of larger vessels, the hepatic veins empty into the inferior vena cava.

The hepatic artery is distributed mainly to the fibrous tissue of the capsule and interlobular septa. Its terminal branches join the hepatic sinusoids. The blood conveyed to the liver by the hepatic artery constitutes about 25 per cent of the organ's total blood supply. Upon this fraction, however, the liver depends for its oxygen supply; the oxygen saturation of the portal blood is low and probably gives up little oxygen in its passage through the liver. For this reason necrosis of

FIG. 128. Diagram of the hepatic circulation. Two Kupffer cells are shown in a sinusoid.

the liver and death follow shortly after ligation of the hepatic artery.

The blood pressure in the portal vein, as measured in experimental animals, is from 8 to 12 mm. Hg. In the dog and probably in man the muscular coat of the hepatic veins near their entrance into the vena cava is highly developed. When contracted the smooth muscle in this situation, which Dale and his associates refer to as the "hepatic sphincter," may cause a marked increase in the resistance to the hepatic blood flow. Through this arrangement the hepatic veins serve the purpose of an adjustable sluice by means of which the quantity of blood in the liver is varied considerably under different conditions. The liver thus functions as a reservoir within which blood at one time may be pooled, or from which at another time an extra quota of blood may be

delivered into the general circulation. Barcroft, Nisimaru and Ray point out, however, that the liver is not a storehouse in the sense that the blood is in a cul de sac and out of circulation, as in the case of the spleen (p. 53). The time taken for a red cell to traverse the hepatic channels (6 to 10 seconds) is only a fraction of the time that it spends in passing through the spleen or even of the skin. It was found, for example, that 30 minutes after an animal had breathed carbon monoxide, samples of blood taken from the femoral artery, portal vein, hepatic veins and from the scratched surface of the liver had all practically the same CO saturation. That is, there had been no greater retention of CO by the hepatic blood, and consequently no significant slowing of the flow through the liver.

The "hepatic sphincter" is constricted by peptone and histamine, and relaxed by adrenaline or sympathetic nerve impulses. The great engorgement of the liver and splanchnic area in dogs following histamine poisoning (histamine shock) is illustrative of the effect of this drug upon the hepatic veins. The splanchnic congestion seen in anaphylactic or peptone shock in this species, is also due, apparently, to constriction of the hepatic veins and the damming back of blood in the portal system. Adrenaline, on the other hand, according to the observations of Rein and his associates, causes the immediate delivery from the liver into the general circulation, of a weight of blood equal to from 26 to 59 per cent of the weight of the liver itself.

The blood flow through the liver is also varied through nervous influences acting upon the intrahepatic vessels and upon the vessels of the splanchnic area. Variations in the caliber of the former will alter the resistance to the flow through the liver. Variations in diameter of the splanchnic vessels, on the other hand, increase or diminish the quantity of blood entering the portal tributaries.

OBSTRUCTION OF THE PORTAL CIRCULATION

In cirrhosis of the liver (portal cirrhosis), the compression of the intrahepatic vessels by fibrous tissue raises the resistance to the flow of blood through the liver. As a result of the rise in pressure in the portal system, the blood is forced into channels, inconspicuous under normal conditions, connecting the portal vein and the systemic veins. The chief among these by-passes for the return of blood from the splanchnic area to the right auricle are provided by anastomoses between

(a) the coronary vein of the stomach and the esophageal veins, (b) the superior hemorrhoidal branches of the inferior mesenteric vein and the middle and inferior branches of the internal iliac (hypogastric) veins, (c) the epigastric veins (superior and inferior) and the portal vein through the para-umbilical vein of Sappey; when these communications are fully established the epigastric veins appear as a group of large tortuous vessels in the abdominal wall in the region of the umbilicus (*caput medusae*); (d) the radicals of the portal vein in the intestines and the inferior vena cava, through the retroperitoneal veins of Retzius.

ECK FISTULA. This is the communication produced for experimental purposes between the portal vein and the inferior vena cava. The two veins are anastomosed side by side and the portal vein then ligated between the anastomosis and the liver; the blood from the portal area is thus turned directly into the vena cava. The hepatic artery is, of course, left intact. This operation has been employed in certain studies where it has been desired to exclude hepatic function. Such an object is not attained, however, for the only satisfactory means of abolishing the function of the liver is to remove it.

EXTIRPATION OF THE LIVER. Ordinarily, death occurs within a very short time after removal of the liver. The rapid death is not due to the loss of the essential hepatic functions, but simply to the fact that since the portal vein must be tied, the return of blood from the splanchnic area to the systemic circulation is blocked. The vessels of the intestines and spleen become intensely engorged, the animal dying as a result of the great reduction in its circulating blood volume, or, as the expression goes, it bleeds into its own splanchnic vessels.

Mann and Magath have devised a three-stage operation which makes it possible to remove the liver completely from dogs and have them survive for periods varying from 20 to 36 hours. The first stage of the operation consists of anastomosing the portal vein and the inferior vena cava and ligating the latter vessel above the anastomosis, but below the entrance of the hepatic veins. All the blood from the lower part of the body is thus directed to the liver. This *reverse Eck fistula*, as it is called, and the consequent great increase in the blood flow to the liver, elevates the portal venous pressure. Anastomotic channels gradually open up between the portal and systemic systems through which a large part of the blood is diverted. After a few weeks when the collateral circulation

has become well established, the portal vein is tied. The final operation, performed after the lapse of another two weeks, consists of tying the hepatic artery and removing the liver, which has now shrunk considerably in size.

Markowitz and Soskin have developed a simplified technique for the removal of the liver which does not involve the anastomosis of the portal vein to the vena cava. They apply ligatures to these vessels which constrict, but do not completely occlude them. The increased resistance thereby induced results in the development of the collateral channels. After these have become established the portal vein and inferior vena cava are completely occluded, and the liver removed in the usual way.

It is also possible to extirpate the liver at one sitting (Markowitz and colleagues) by connecting the infra- and supra-hepatic sections of the vena cava by means of a cannula of pyrex glass (which, as shown by Firor, does not cause blood clotting). The vena cava below the liver is opened. The cannula is inserted into the vein and passed upward through its intra-hepatic portion into the supra-hepatic portion; the vein is then tied around the lower end of the cannula. The portal vein and inferior vena cava are next anastomosed. The vena cava is then tied around the upper end of the cannula. Finally, the portal vein and hepatic artery are ligated and the liver removed, the hepatic tissue being stripped away from the reconstructed vena cava.

THE CEREBRAL CIRCULATION

ANATOMICAL DESCRIPTION

Blood enters the cranium through the *internal carotids* and the *vertebral arteries*. The brain of man receives the greater part of its blood supply through the internal carotids. The two vertebrals unite to form the *basilar artery* which runs forward in the median groove on the under surface of the pons and divides into the two *posterior cerebral arteries*. Each internal carotid divides near the lateral border of the optic chiasma into the *anterior* and *middle cerebral arteries*. Communicating vessels unite the posterior and middle cerebrals on either side and the two anterior cerebrals. Thus a vascular ring—the *circle of Willis*—is formed at the base of the brain around the optic chiasma, the tuber cinereum, infundibulum and corpora mammillaria. Through the circle of Willis very free communication between the internal carotids and the vertebrals is established. Owing to the presence of these anastomotic channels both carotids can be tied in the monkey without serious interference with the blood supply to the brain. Ligation of both carotids and one vertebral in this animal results in stupor and death. The dog survives after both internal carotids and the two vertebrals near their origins have been ligated. Blood then reaches

the circle of Willis through anastomoses between the spinal branches of the vertebrals and the deep cervical artery; and also, as shown by Bouckaert and Heymans, through an ophthalmic branch of the internal maxillary artery (branch of external carotid) which communicates with the internal carotid within the skull. This latter communication is capable of maintaining the viability of the brain, though all other channels through which blood could enter the cranial cavity have been tied. The extent to which the main arteries to the human brain can be occluded is not definitely known. In most instances, ligation of one common carotid in man causes no ill effects owing to the rich anastomoses between the two external carotid and between the external carotid with the internal carotid of the opposite side. Syncope, convulsions, etc. reported as resulting from compression of one common carotid were in all probability due to a sinus reflex (p. 241) rather than to mechanical interference with the cerebral blood supply. Compression of both common carotid arteries in man is followed within a few seconds by unconsciousness.

The anterior and middle cerebral arteries, branches of the internal carotid, and the posterior cerebral branches of the basilar, after giving off branches which supply chiefly the basal ganglia and hypothalamus, pass to the surface of the cerebrum. Here they ramify in the pia mater and send twigs into the underlying substance of the hemispheres. The anterior cerebral courses forward from its origin to the commencement of the longitudinal fissure and then arches backward over the corpus callosum. It is distributed over the medial surface of the frontal and parietal lobes; an adjacent band of cortex on the lateral aspect of the hemisphere; and the cortex of the cingulate gyrus. The middle cerebral artery reaches the surface of the hemisphere through the Sylvian fissure. Among its basal branches are twigs—*lenticulo-striate*—to the lentiform nucleus and internal capsule. One of these, larger than its fellows, not infrequently ruptures and on this account is referred to as the "artery of cerebral hemorrhage." The cortical distribution of the middle cerebral includes the anterior pole of the temporal lobe; the lateral part of the orbital surface of the frontal lobe, the insula; and the large area of the lateral surface of the hemisphere not supplied by the anterior or posterior cerebrals, that is, the greater part of the middle and inferior frontal gyri; the lower two-thirds of the pre- and post-central gyri; the supramarginal and angular gyri; and the superior and middle temporal gyri. The posterior cerebral artery curves backwards between the cerebral peduncle and the uncus. It supplies the uncus and hippocampal gyrus on the medial aspect of the hemisphere, the fusiform and inferior temporal gyri, and the cortex on the medial, inferior and lateral surfaces on the occipital lobe.

The vertebral artery on each side gives off a little below the pons a *posterior inferior cerebellar* branch which supplies the medulla. It sends twigs to the glossopharyngeal, vagus and accessory nuclei; to the

spino-thalamic, spino-cerebellar and rubro-spinal tracts; and, probably, to the spinal root of the trigeminal nerve. The basilar artery, formed by the union of the two vertebrals gives off on each side an *anterior inferior cerebellar* branch which ramifies over the under surface the cerebellar hemisphere, and a *superior cerebellar* branch which is distributed to the superior surfaces of the vermis and cerebellar hemisphere.

The blood is returned from the brain through the *cerebral veins* which course over the surface of the hemispheres, and receive as tributaries the small veins which drain the capillary bed in the brain substance. The cerebral veins drain into the large *dural sinuses*—*superior and inferior sagittal, cavernous, straight*, etc.—which lie enclosed between the outer and inner layers of the dura mater. The sinuses possess no valves. Their triangular cross-section and the support afforded by their dural envelopes render them relatively resistant to compression. The venous blood ultimately finds its way into the two *transverse sinuses*. The transverse sinus on either side becomes continuous at the jugular foramen with the internal *jugular vein*.

The network of veins which begins with the dural sinuses in the posterior cranial fossa forms a longitudinal plexus which extends throughout the entire length of the spinal column and communicates at each intervertebral space with veins within the thorax and abdomen. This plexus constitutes a route through which the blood can be returned from the cranial cavity to the superior and inferior venae cavae. That this alternative channel is of great functional importance in man is shown by the fact that both internal jugulars can be ligated simultaneously without serious consequences. Even complete occlusion of the superior vena cava by a thrombus may occur with relatively little ill-effect. Other less important channels through which blood may be returned from the cranium are, the emissary veins of the skull which connect the dural sinus with the veins of the scalp, and communications between the veins of the orbit and the pterygoid plexus of veins.

The gray matter is much more vascular than the white matter. In the human cerebral cortex the total capillary length is about 1 meter per cu. mm. of tissue, and only around 200 mm. per cu. mm. in the underlying white substance. The cerebral vessels are not "end arteries" but form a continuous, freely communicating network through which a corpuscle might travel from the frontal to the occipital lobe.

FACTORS REGULATING THE CEREBRAL BLOOD FLOW

The adult cranial cavity and vertebral canal form a space which is almost completely enclosed by rigid walls and filled by brain substance, cerebro-spinal fluid and blood. The total volume of the cranial contents, which are incompressible, can therefore alter relatively little and to an extent which is determined simply by the degree of

bulging of the membranes at the occipito-atlantoid joint and between the vertebrae.⁷ Nevertheless, under certain circumstances considerable reciprocal volume changes between the brain substance, cerebro-spinal fluid and blood may occur. The intravenous injection of hypertonic (30 per cent) saline, for example, causes, through the changes in osmotic relationships, a shrinkage of the brain, a fall in cerebro-spinal fluid pressure from around 10 mm. Hg to a negative value (-10 mm. Hg), but a very moderate fall in the pressure of blood in the superior sagittal sinus. As a consequence, reversal of the normal relationship between cerebro-spinal fluid and venous cerebral pressures results, the former being reduced considerably below the latter. The creation in this way of a negative cerebro-spinal fluid pressure is strong evidence that the cranial contents are contained within a "closed box." Hypotonic solutions cause an increase in brain volume and a rise in cerebro-spinal fluid pressure and of the pressure in the superior sagittal sinus; the normal relationship between cerebro-spinal fluid and cerebral venous pressures is therefore maintained.

The vessels of organs such as the kidney, liver or muscles, etc., can dilate widely and the whole organ expand (see fig. 114, p. 252). Consequently a greater mass of blood can be held by these structures at one time than at another, and it is possible for a greater volume of blood to flow through them without the velocity of flow through the individual vessels being increased. Since the mass of intracranial blood cannot be much greater at one moment than another, a greater oxygen supply to the brain is assured largely by an increase in the speed of the blood through the individual vessels rather than by an enlargement in the total capacity of its vascular bed. The cerebral circulation time (carotid to jugular by the radium emanation method) is around 3 seconds.

The velocity of the blood through the intracranial vessels is determined by the pressure difference (pressure gradient) between the cerebral arteries and the cerebral veins. The pressure in the former vessels is ordinarily proportional to the systemic arterial pressure. The pressure in the larger cerebral arteries is about 65 mm. Hg

diastolic, and 100 mm. Hg systolic. The pressure in the capillaries is about 13 mm. Hg. The pressure in the intracranial veins though lower than, varies with, the cerebro-spinal fluid pressure. The venous pressure in the recumbent position is from 6 to 8 mm. Hg, i.e., approximately the same as the pressure in the median basilic vein, but becomes reduced nearly to zero in the erect position. Changes in venous pressure at the right auricle are transmitted to the jugular vein and so to the intracranial veins. In consequence, the pressure in the venous sinuses varies as a result of the changes in intrathoracic pressure occurring during the respiratory cycle—increasing during expiration and decreasing during inspiration. Failure of the right ventricle, thrombosis of the transverse sinus or obstruction of the jugular vein, or of the superior vena cava, are among some of the pathological conditions which result in an increase in the cerebral venous pressure. A fall in arterial pressure or a rise in cerebral venous pressure will tend to slow the blood flow through the brain; reverse changes will tend to increase the cerebral blood flow. However, apart from the postural and respiratory variations just mentioned the cerebral venous pressure remains fairly constant under ordinary conditions. The intracranial blood flow is, therefore, determined largely by the height of the general arterial blood pressure. Until recently this was considered to be the sole factor regulating the flow through the brain; the cerebral vessels themselves were thought to play a purely passive rôle.

Next to the systemic blood pressure, the gas tensions of the blood constitute the most important factors in the control of the cerebral circulation. Carbon dioxide has a profound dilator effect upon the pial vessels; it is capable of causing changes in vascular calibers independently of alterations in the general blood pressure, and by dilating the vessels may increase the cerebral blood flow by 40 per cent. Anoxemia has been found by most investigators to exert a much less potent vasodilator effect; an increase in oxygen tension causes a slight decrease in blood flow through the brain.

The results of Schmidt's investigations have thrown doubt upon the generally held view that carbon dioxide is a powerful dilator of the cerebral vessels. The experiments upon which this belief is based were mostly upon cats and total cerebral blood flow was not determined. Dumke and Schmidt measured the total blood flow in the monkey and found that raising the CO_2 content

⁷The conception of the invariability of the volume of the intracranial contents as a result of the rigidity of the cranial boundaries, originated with Alexander Monro of Edinburgh (1783), and was elaborated by Kellie (1824); it is therefore commonly known as the Monro-Kellie doctrine.

of the inspired air only slightly increased the cerebral blood flow, and that changes in the oxygen content caused more consistent and more pronounced effects. These results have been confirmed, and mean either that previous determinations of changes in blood flow in the cat were not representative of what occurs in the vessels of the brain as a whole, or that species difference exists. If the latter alternative is the correct one, since man is closer philogenetically to the monkey than to the cat, the experimental results of these authors are of greater importance.

THE NERVOUS CONTROL OF THE CEREBRAL VESSELS. Gulland nearly forty years ago (1898) reported having discovered nerve filaments upon the blood vessels of the pia mater; Huber a year later described medullated and non-medullated nerves ending on these vessels. He considered the medullated filaments to be sensory, the non-medullated, vasomotor in function. Nerve fibers going to the blood vessels within the brain substance have also been described by others (Kolliker, Clarke) and more recently by Penfield.

Though Wiggers had demonstrated that the pial vessels reacted to adrenaline by constriction, it is only within the last few years that definite evidence of the nervous control of the intracranial vessels has been secured; it is now definitely established that vasoconstrictor impulses are conveyed by the sympathetic; vasodilatation follows stimulation of the central end of the vagus (see below).

The pial vessels have been observed by Forbes and Wolff through a glass window screwed into a trephine hole in the skull, the space between the glass and the brain surface being filled with Ringer's solution. Upon stimulation of the sympathetic, constriction of pial and dural vessels was observed accompanied by a rise in systemic arterial pressure; section of the sympathetic was followed by dilatation of the exposed vessels. Stimulation of the central end of the cut vagus, aortic or sinus nerves or of the facial nerve at the geniculate ganglion, resulted in dilatation of the pial vessels and a fall in systemic pressure. The vessels of the pia mater were not altered in caliber by a rise in the systemic arterial blood pressure unless this exceeded 60 mm. Hg; dilatation of the vessels apparently passive in nature was then observed. These experiments show that the superficial cerebral vessels can constrict or dilate quite independently of, or indeed in spite of, a rise or a fall in systemic pressure, and prove conclusively the existence of a nervous mechanism

in the control of the intracranial circulation. This control is not essentially different from that governing the caliber of the systemic vessels except that the cerebral vessels, according to Schmidt, are held in a state of tonic dilatation rather than in one of tonic constriction as prevails in the vascular system of the rest of the body. Reduction of vasodilator tone is probably of greater importance than sympathetic impulses in bringing about constriction of the cerebral vessels.

A fall in systemic blood pressure below a certain critical level (about 60 mm. Hg) causes dilatation of the cerebral vessels. This reaction apparently constitutes a safety device to maintain an adequate blood supply to the brain. The associated fall in blood pressure has been shown to be the factor responsible for the vasodilatation caused by stimulation of the vagus, aortic or sinus nerves (Forbes and associates), for vasodilatation fails to take place if the blood pressure is prevented from falling while the nerve is stimulated. On the other hand, the vasodilator response is not altered by the application of cocaine to the pial vessels, which indicates that it is not a true reflex but a reaction of the vascular walls themselves to the low intravascular pressure. Since vasodilatation following vagal excitation is simply a compensatory response to the fall in blood pressure it rarely causes any increase in cerebral blood flow. The cerebral vasodilatation caused by stimulation of the facial nerve occurs with a normal blood pressure and is abolished by cocainization of the pial vessels. It therefore appears to be a direct reflex response of the vessels to nerve stimulation. The vasodilator fibers of the facial pass to the vessels via the geniculate ganglion, the great superficial petrosal and the internal carotid nerves. *The facial is apparently the only nerve carrying dilator fibers to the cerebral vessels.*

The observations just described are not incompatible with the conception that the quantity of blood within the cranial cavity remains *approximately* constant. For, changes in the calibers of the vessels in one area of the brain may coincide with changes of an opposite character in another,*

* A number of observations support the idea of regional variations in cerebral blood flow in accordance with functional demands. For example, Fulton observed in a patient that the blood flow of a vascular tumor (hemangioma) of the occipital lobe increased (as indicated by an accentuation of the bruit heard over the occipital bone) when the subject read fine print. Also, in animals a thermocouple in the optic pathway records a rise in temperature when the eyes are illuminated; on the other hand, when the skin of

and, since the spinal column does not constitute a completely rigid encasement but contains distensible structures, small reciprocal changes in cerebro-spinal fluid may allow corresponding variations in vascular diameters. During sympathetic stimulation an average reduction in diameter of 8.5 per cent occurs and during vagal stimulation an average increase in diameter of 22 per cent. The dilatation of even a relatively large number of arterioles to this extent might cause little increase in the total quantity of blood contained at any instant within the cranium. Nevertheless, a very considerable increase in blood flow might result, for, according to Poiseuille's law (p. 114) the flow of liquid through a capillary tube (other factors remaining constant) is directly proportional to the fourth power of the diameter of the tube. Thus an increase of 22 per cent in vascular diameters would increase the blood flow 150 per cent (Cobb).

These facts throw a new light upon the physiology of the cerebral circulation. They indicate that with a constant systemic arterial blood pressure, changes in blood flow not only through one part of the brain in relation to another part, but through the brain as a whole may be brought about. Finesinger and Putnam, for example, perfused the brains of monkeys through the internal carotid with heparinized blood after tying the vertebrals and the opposite carotid. The minute volume of the inflow was measured while the sympathetic or vagus was stimulated, the perfusion pressure being maintained constant. Sympathetic stimulation reduced and vagal stimulation increased the inflow. It was found, however, that variations in the perfusion (carotid) pressure were more effective in varying the blood flow than was nerve stimulation with a constant pressure head. The maximum blood flow through the brain would of course result from a rise in systemic pressure accompanied by dilatation of the cerebral vessels. In this connection may be cited the observations of Heymans and Bouckaert. These observers found that a pressor reflex elicited from the carotid sinus did not involve the cerebral vessels. In this reflex the rise in blood pressure, due to vasoconstriction of the

the feet was stimulated, though there was no indication of increased flow in the optic pathways, a definite temperature rise was recorded from nervous tracts subserving cutaneous sensations (Gerard and Serota) and, during muscular movements, from the motor cortex. Increased vascularity, as demonstrated by intravital injections of dye, is found in the olfactory lobes of the cat after the inhalation of a strong-smelling gas.

systemic arterioles, must obviously result in a greater flow through the cerebral vessels than would occur if these shared in the vasomotor response.

Alterations in the blood flow through the human brain can be determined from comparisons of the oxygen (or carbon dioxide) contents of the blood entering and leaving the cranial cavity. Blood samples are taken from an artery and the jugular vein. An increase in the arterio-venous oxygen (or carbon dioxide) difference⁹ indicates a reduced blood flow; a lowered arterio-venous oxygen (or carbon dioxide) difference (i.e., jugular blood more arterial in character) indicates an increased flow. Variations in the intracranial blood flow of the human subject can also be demonstrated by inserting an electrically heated needle into the jugular vein, and measuring fluctuations in its temperature by means of thermocouples connected in series with a galvanometer. The heated element is cooled by the blood flowing around it, a rise or fall in its temperature, therefore, indicates a reduced or an increased blood flow respectively.

Ferris has attempted to measure the total blood flow through the human brain by an ingenious plethysmographic method (see p. 149). A wide-bore needle is introduced into the lumbar subarachnoid space, the cerebral blood flow is estimated from the displacement of cerebrospinal fluid while the jugular veins are occluded for a brief period by means of a pressure cuff encircling the neck. The total cerebral blood flow in man, as measured by this method, is 250 cc. per minute during rest and 400 cc. maximum, or 16 cc. and 26 cc. per 100 grams of brain substance per minute. Owing to certain sources of error in this method (e.g., the escape of blood from the craniovertebral cavity through unoccluded veins) this estimate is probably much too low. Dumke and Schmidt obtained a higher figure for the monkey, namely, 60 and 110 cc. per 100 grams of brain per minute.

The demonstration that the cerebral vessels can vary their calibers independently of changes in systemic blood pressure also provides a physiological basis upon which temporary disturbances in cortical function may possibly be explained. It has long been suspected, for example, that transient hemiplegia, amblyopia, and possibly migraine or convulsive seizures, may be due to

⁹ Under ordinary circumstances this is high, namely, about 8 volumes per cent (coefficient of oxygen utilization around 0.4).

spasm of pial vessels and a consequent anemia of the cerebral centers. Attempts to gain information upon this question have been made by studying the effects of convulsant poisons in animals. Finesinger and Cobb observed acute constriction of the pial vessels preceding the convulsions induced by the intravenous injection of caffeine; but only vasoconstriction preceded the convulsions caused by the administration of picrotoxin or small doses of absinthe and vasodilatation resulted from the administration of a convulsive dose of camphor or of a large dose of absinthe. Nor does it appear that the convulsive action even of those drugs which cause pial vasoconstriction is directly due to reduced cerebral blood flow. Gibbs, for example, found that convulsions followed the administration of caffeine though the blood flow was increased by injecting adrenaline (see below). The general belief that cerebral anoxia causes an initial stimulation of nervous tissue with the production of convulsions, has been disputed by Schmidt who maintains that oxygen lack always depresses cerebral functions.

THE ACTIONS OF CERTAIN CHEMICALS AND DRUGS UPON THE CEREBRAL VESSELS

Histamine dilates the pial vessels and raises the cerebro-spinal fluid pressure. Flushing of the cortex has been observed in man following its administration; this is probably the cause of the intense but transient headache which sometimes follows an injection of histamine. Weiss and Lennox showed also that the arterio-venous oxygen difference was reduced, i.e., the intracranial blood flow was increased, by histamine. Since the systemic blood pressure remained practically unaltered, dilatation of the cerebral vessels must have occurred. *Metrazol*, *ether*, *alcohol* and *carbon monoxide* are also dilators of the pial vessels. *Adrenaline* applied locally to the surface of the brain causes vasoconstriction. Its injection into the general circulation, however, is followed by vasodilatation. This is a passive effect due to the rise in blood pressure, that is, the latter overcomes the local effect of the hormone upon the pial vessels. The net result of adrenaline liberation under physiological conditions is therefore an increase in cerebral blood flow. *Benzedrine* given by intracarotid injection reduces the blood flow to the brain. *Pitressin* has an inconstant effect but in most instances causes cerebral vasoconstriction. *Acetylcholine* is vasodilator but, owing to its causing a coincident fall in blood pressure, little or no increase in blood flow results; it may even cause a reduction. Most *anesthetics*, especially *ether*, cause vasodilatation. *Hypertonic solutions* administered intravenously cause a brief period of vasoconstriction followed by an increased blood flow. This is apparently due to the well-known action of such solutions in reducing the intracranial pressure and in causing a rise in systemic arterial pressure. *Caffeine* in large doses decreases the cerebral blood flow. *Amyl*

nitrite dilates the cerebral arterioles as it does those of the rest of the body. There are very few agents known which constrict the cerebral vessels. Among them are *barium chloride* and, as already mentioned, a high tension of oxygen. A low CO_2 tension, of course, results in vasoconstriction.

THE EFFECT OF INCREASED INTRACRANIAL PRESSURE UPON THE CEREBRAL CIRCULATION

Forbes and Wolff studied in cats the effects upon the cerebral circulation of raising the intracranial pressure. They introduced Ringer's solution under pressure into the cisterna magna and observed the superficial vessels through a glass window fixed into the cranial wall. It might be thought that any considerable rise in intracranial pressure would compress the cerebral veins and arrest the circulation. No change in the vessels of the pia mater could be detected, however, until the cerebro-spinal fluid pressure had been increased to a value four or five times that of the normal. With gradual elevation of the pressure the sequence of vascular events was;—slowing of the blood flow in the veins, then dilatation of their lumina; dilatation of the arteries, slowing of the arterial blood flow, narrowing of the arteries; and finally, complete obliteration of the vessels with consequent blanching of the cortex. It appears that as the cerebro-spinal fluid pressure rises, the pressure is transmitted to the blood in the veins and through these vessels to the capillaries and arteries. Thus, though at first no change in systemic arterial pressure occurs, a higher arterial pressure is established within the cranium and the difference between arterial and venous cerebral pressures is maintained. The cerebral circulation, though slowed, is able to continue despite a high cerebro-spinal fluid pressure. When the cerebro-spinal fluid pressure equals the systemic arterial pressure the circulation through the cerebral vessels, of course, becomes impossible.

The "local" rise in arterial pressure accounts for the fact that in clinical cases in which, though the intracranial pressure is considerably elevated and the systemic arterial pressure unaltered, the circulation through the brain is not cut off. It has been shown by Berens and his associates that in subjects of brain tumor a rise in the pressure in the retinal arteries may occur unaccompanied by any elevation of the systemic pressure. When the cerebro-spinal pressure continues to rise and the pressure in the cerebral arteries approaches that in the systemic vessels, the intracranial blood flow must be seriously curtailed and finally arrested unless further adjustments occur. These are brought about through the vasomotor center; the slowing of the flow through the medulla stimulates the center; a rise in systemic blood pressure results to force blood through the cerebral vessels threatened with obliteration.

SECTION III. RESPIRATION

CHAPTER XXIX

INTRODUCTION

THE MECHANICS OF RESPIRATION

The term "respiration" refers to the gaseous interchange between an organism and its environment. The more obvious chemical features of this process are the absorption of oxygen and the elimination of carbon dioxide. All living things, excluding certain microorganisms which secure energy from dehydrogenase or similar systems, must be supplied with oxygen. The oxygen is absorbed by the blood in the lungs for delivery to the tissue cells wherein carbon is oxidized to carbon dioxide and hydrogen to water. The CO_2 is transported by the blood to the lungs and eliminated in the expired air. The exchange of the respiratory gases between the tissue cells and the internal environment, which is constituted by the fluids bathing the cells, is called *internal respiration*. This process is essentially the same as that taking place between unicellular organisms (e.g., the amoeba) or primitive multicellular forms and the aqueous environment in which they live. The exchange of oxygen and carbon dioxide between the blood in the pulmonary capillaries and the air in the lungs is termed *external respiration*. The study of respiration therefore involves, principally, (1) the physiological mechanisms responsible for the body obtaining an adequate supply of oxygen from the external environment, (2) the transport of oxygen from the lungs to the tissues and of carbon dioxide to the lungs, (3) the exchange of the respiratory gases between the cells and the internal environment, (4) the oxidative and other respiratory processes within the tissue cells whereby energy is liberated, and (5) the control of these mechanisms and their correlation with one another and with other bodily processes.

Physiological anatomy

Air entering through the nasal openings is warmed and some of the grosser impurities are retained by the fine hairs around the nostrils and by the mucous secretion. The nasal cavity just within the external nares (vestibule) is lined with skin. The remaining parts of the nasal cavities are lined with mucous membrane which is covered by a layer of ciliated columnar epithelial cells and scattered "goblet" cells; it is continuous

with the membrane lining the accessory nasal sinuses. (The nasal lining is very vascular; it contains a venous plexus whose channels anastomose freely and give the mucosa an appearance suggestive of erectile tissue. The vascular channels are dilated by several conditions, e.g., infections, local irritants, certain anaphylactoid states and a rise in temperature of the inspired air; the mucosa swells and the airway is narrowed in consequence. Cooling the inspired air causes their constriction, as will also the application of adrenaline or ephedrine to the mucosa. The vascularity of the mucosa is also influenced reflexly by the application of heat or cold to the skin of remote regions of the body.) Leonard Hill has postulated a remarkable effect of infra-red rays applied to the skin in altering the diameter of the nasal airway. The effective or "nose closing" rays are said to be those given out by a dull red or dark source of heat (waves over 30,000 Ångström units in length). The interpretation of these results and others more recently reported by Hill on "nose opening" rays has been seriously challenged by other workers in this field. The present position is that the problem awaits thorough investigation. [The pharynx is, of course, a common pathway for food and air. As the food passes the laryngeal opening this is closed by reflex action and respiration is inhibited. The surface epithelium of the nasal part of the pharynx is provided with cilia and goblet cells. In the oral part of the pharynx the epithelium is of the stratified squamous type. The epithelium of the bronchial tree presents very definite changes as one proceeds from the larynx to the terminal bronchioles. The stratified squamous covering of the upper part of the larynx changes to ciliated in the lower part of the vestibule of this organ. The vocal cords are covered with squamous epithelium, but ciliated cells again line the trachea. The epithelium of the trachea contains also goblet cells and mucous and serous glands. The large bronchioles are similar to the trachea in this respect, but in the bronchioles the goblet cells and deep glands are lost.]

CILIA. The nasal secretions are moved toward the nostrils mainly by the action of cilia. It is perhaps not generally appreciated that the sinuses are kept clear, under normal conditions, by the beating action of the cilia with which the epithelium is very plentifully supplied. As stated above, ciliated cells are found in the nasal part of the pharynx, in the lower part of the vestibule of the larynx and in the trachea.

The cilia beat with a motion which propels material toward the mouth. They become even more abundant when the large bronchioles are reached, but are largely replaced by cuboidal or flattened cells in the respiratory bronchioles.

The efficiency of the ciliated cells of the trachea and large bronchioles in propelling mucus and waste material orally is, under normal conditions, of a high order. The cilia are not influenced by nerve impulses, but are very susceptible to chemical changes in the blood and to substances applied locally. Certain general anesthetics depress their activity and many sedatives exert the same effect. Ciliary action is depressed by cold and increased when the temperature of the cells is

probably in large part for the recoil mechanism of the whole lung. The importance of this elastic recoil will be stressed again later. In the larynx, cartilage supports the special structures necessary for the attachment of the vocal cords and the functioning of the glottis. The cartilaginous rings in the trachea are incomplete on the posterior aspect. This arrangement provides for some contraction of the trachea, but the lumen cannot be obliterated as is the case with the small bronchioles.

MUSCLE. The ends of the cartilaginous rings of the trachea may be approximated by the action of the transverse smooth muscle fibers. In the bronchi the bands of fibers tend to become circular and this is seen

FIG. 129. Guinea-pig. Showing the broncho-constrictor effect of stimulating the vagus of the same side. The effect lasts after stimulation has ceased. Atropine in moderate dose had a very slight dilator action; adrenaline in small quantity caused marked bronchodilatation. During this action further stimulation of the vagus had an almost negligible effect. (After Thornton.)

raised slightly above normal. The efficiency of the cilia depends in part on the viscosity and stickiness of the material which is in contact with them. Their effectiveness may be varied by changing the properties of this material as well as by increase or decrease in the rate or force of beating. The motion of the cilia is wave-like and has been well compared to the undulation of a field of wind-swept grain. The individual cilium moves, in the direction in which its force is exerted, with a whip-like motion and then relatively slowly returns to its former position.

ELASTIC TISSUE. The bronchial tree is rich in elastic tissue, most of the fibers being disposed longitudinally in the tunica propria. This elastic membrane, which extends throughout the trachea, bronchi and bronchioles right to the alveoli, is responsible for the recoil of the bronchial tree during expiration and

even more definitely in the bronchioles. The amount of muscle is reduced in the respiratory bronchiole and does not extend beyond this subdivision of the bronchial tree.

BLOOD SUPPLY. The bronchial tree, as far as and including the respiratory bronchioles, is supplied by a rich plexus of vessels derived from bronchial arteries—branches of the thoracic aorta. The blood is collected by the bronchial veins which in the case of the right lung empty into the azygos vein. Those from the left lung are tributary to the left superior intercostal vein (or sometimes to the accessory hemiazygos vein). The respiratory part of the lung receives its blood from the pulmonary artery, the blood being returned via the pulmonary veins to the left side of the heart. Anastomoses between the pulmonary and systemic systems of vessels occurs, however, in the walls of the

respiratory bronchioles, so that the blood from this region of the bronchial tree is returned in part to the right side of the heart and in part to the left.

NERVE SUPPLY OF THE BRONCHIOLES. Excitor (broncho-constrictor) fibers to the bronchiolar muscle are derived from the vagus, and inhibitor (broncho-dilator) fibers from the sympathetic. Afferent fibers from the lungs run in the vagus. The nerve supply to the pulmonary vessels is considered on page 284. The bronchioles are constricted by pilocarpine, histamine and by certain foreign proteins (anaphylactic reactions). They are dilated by adrenaline, ephedrine and atropine (figs. 129 and 166, p. 368).

THE BRONCHIOLES AND AIR SACS. Macklin divides the bronchial tree into two parts. The first part which extends from the trachea to the *terminal bronchiole* inclusive, serves simply as an air-conduit and, like the branches and twigs of a tree, possesses no respiratory function. The terminal bronchiole is simply the last of a series of subdivisions of these non-respiratory bronchioles. The muscle in its wall is more highly developed than in any other part of the bronchial tree and when fully contracted exerts a sphincter-like action which can completely shut off the air supply to the air chambers beyond.

The structures lying distal to the terminal bronchiole are the "leaves" of the bronchial tree. They are respiratory in function, i.e., an interchange of gases between lung air and blood occurs across their walls. This part consists of (a) the *respiratory bronchioles*, (b) *alveolar ducts*, (c) *alveolar sacs*, and (d) *pulmonary alveoli*. The cluster formed of these structures together constitutes a *lung-unit* or *primary lobule* (i.e., the group of structures which like the nephron or renal unit carries out the specific function of the organ). It is the distensible or bellows part of the lung.

The *respiratory bronchiole* has the same diameter as the terminal bronchiole, of which it appears as a branch or a continuation. The *alveolar ducts*, five or six in number, arise from each respiratory bronchiole (fig. 130). Each alveolar duct after a variable number of rebranchings gives rise to from 3 to 6 dilatations, the *alveolar sacs*. The bays in the walls of the latter constitute the *pulmonary alveoli* which are lined by a single layer of flattened epithelial cells cemented together. The alveolar walls contain elastic fibers and a rich network of capillaries. Frequently a single capillary channel alone intervenes between the walls of adjacent alveoli. The blood in the capillaries is therefore separated from the air in the alveoli by two membranes of the utmost delicacy—the alveolar and capillary walls—so the greatest freedom is afforded for the diffusion of gases from the blood to the alveolar air and from the alveolar air to the blood (Willson; Macklin).¹

¹ The results of Josselyn's recent studies on the anatomy of the alveoli strongly suggest that the alveolar lining may be a discontinuous membrane and that the capillaries are uncovered. In certain areas,

The bronchioles, as they are traced toward the periphery of the lung, branch and rebranch repeatedly, diminishing in length with each subdivision. The first branchings are about 1.5 mm. in length and from 0.3 to 0.4 mm. in diameter. The terminal and respiratory bronchioles are from 0.2 to 0.5 mm. in length, but of about the same diameter as the earlier subdivisions. That is, the bronchioles, though becoming shorter, show practically no decrease in diameter as they pass toward the periphery. The alveolar sac, however, is considerably wider than the respiratory bronchiole or than the alveolar duct from which it arises. The diameter of each pulmonary alveolus which has a semi-globular form is from 0.075 to 0.125 mm. and the total number in the lungs has been estimated by Zuntz at

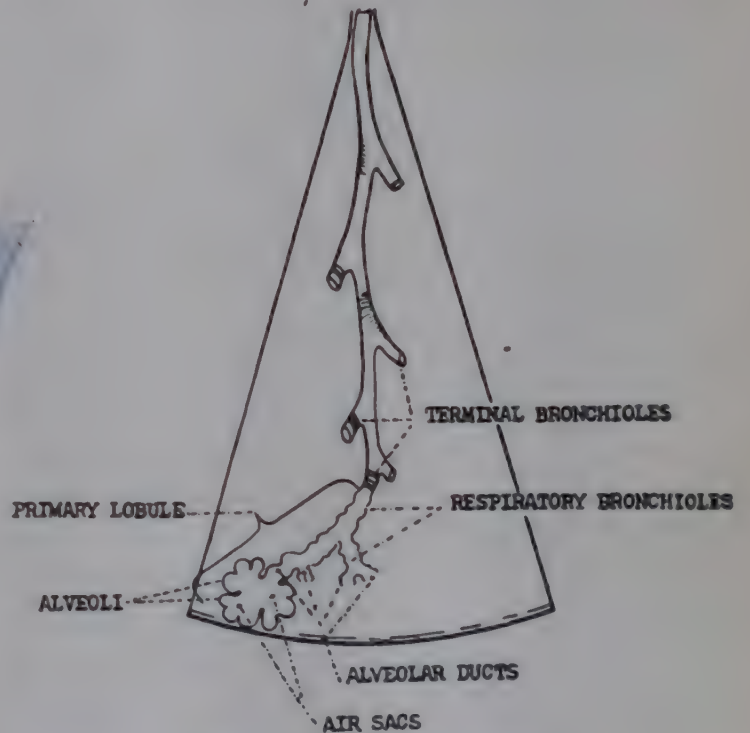

FIG. 130. Description in text.

750 millions. Willson estimates the total epithelial surface of the lungs at 70 square meters. Of this, probably 55 square meters is respiratory; this is over 25 times the surface area of the skin (p. 534).

THE EXPANSION OF THE LUNGS AT BIRTH

Before birth the alveoli contain a small quantity of fluid; the thorax is unexpanded and completely filled by the quite airless lungs. At this time only a small part of the blood of the right heart passes through the lungs. The remainder passes by the ductus arteriosus into the aorta and via the foramen ovale in the interauricular septum to the left heart. Respiratory movements are made by the fetus *in utero*, a fact clearly demonstrated by the work of Barcroft and of Snyder and Rosenfeld. India ink injected into the amniotic sacs of

therefore, the air in the alveoli would be separated from the blood only by the capillary endothelium and a small amount of fluid.

rabbits was found in the alveoli. A movement of amniotic fluid into and out of the fetal lungs appears to be a normal event and probably plays an important rôle in the dilatation of the future air passages. Movements at a rate of about 60 per minute have been observed in the human fetus which are evidently of the same character as those demonstrated in animals. The movements are readily inhibited, especially by anoxemia and narcotics. They are depressed by CO_2 deficit. At the moment of birth the respiratory movements become more forceful, the diaphragm descends and the external intercostal muscles contract with the result that the diameters of the thoracic cavity are very considerably increased (p. 505). A large proportion of the venous blood is now conveyed through the lungs. (The general enlargement of the capacity of the thorax—a closed cavity—tends to reduce the pressure on the outer (pleural) surfaces of the lungs. The greater the degree of enlargement of the chest, the greater will be the reduction in the pressure upon the outer pleural surfaces of the lungs.) The interior of the lungs, however, is in direct communication, through the air passages, with the atmosphere. The visceral and parietal pleurae being inseparable the lungs follow the thoracic wall as it enlarges, and therefore must expand. The rarefaction of the pulmonary air as a result of the expansion results in a flow of atmospheric air into the lungs. Full expansion of the lung is not attained until some few days after birth. The lung throughout the individual's life remains in the expanded position—pressed as it were against the thoracic framework as a result of the greater pressure exerted upon the alveolar than upon the pleural aspects of the pulmonary tissue (p. 298).

Rhythmically alternating increases and reductions of the expanded state of the lungs initiated at birth continue throughout life and constitute respectively the *inspiratory* and *expiratory* phases of respiration. The alternate inflations and partial deflations of the lung are the direct result of corresponding changes in the capacity of the thoracic cavity occasioned by the movements of the diaphragm and other respiratory muscles. Changes in pressure within the lung—the *intrapulmonary pressure*—and upon its pleural surfaces—the *intrapleural pressure*—occur coincidentally with the alterations in lung volume.)

INTRAPULMONARY PRESSURE. In the resting position of the chest the intrapulmonary pressure is atmospheric, but it varies rhythmically with the phases

of respiration, rising above atmospheric pressure during expiration and becoming subatmospheric during inspiration. These variations may be demonstrated by connecting one nostril with a manometer and breathing with the mouth closed. The pressure will be found to be about -2 mm. Hg during the inspiratory phase and to rise to $+3$ or $+4$ mm. Hg during the expiratory phase of ordinary quiet respiration.² The variations are accentuated considerably during forced respiration. The maximal negative pressure capable of being developed within the lungs by a forced inspiration, as when a strong sucking effort is made, is from -40 to -50 mm. Hg. When expiratory efforts are made against a closed glottis, as in coughing, during muscular effort with straining, or during defecation or micturition the intrapulmonary pressure becomes raised by from 10 to 40 mm. Hg. If the free flow of air into and out of the lungs is hindered as a result of some diseased condition the intrapulmonary pressures will be increased beyond the normal range.

THE PLEURAL CAVITIES. (The lungs are invested by the visceral layer of the pleural membrane. The membrane is reflected from the root of each lung on to the inner aspect of the walls of the chest and upper surface of the diaphragm—this is the parietal layer of the pleura.) The two layers thus form a closed membranous sac on each side of the chest. The potential space enclosed by the pleural membranes is spoken of as the pleural cavity. In health *no actual space exists; the two membranes are in apposition* except for a thin film of fluid which serves as a lubricant to allow the surfaces to glide over one another during the respiratory movements. This potential cavity may, however, as the result of disease become an actual one. Serous fluid (hydrothorax), pus (pyothorax or empyema), blood (hemothorax) or air (pneumothorax) may collect and separate the two layers. (Between the two pleural compartments lies the *mediastinum*, a space which is subdivided by the heart with its pericardial investment into an anterior and a posterior part—the *anterior* and *posterior mediastina*.)

A simple puncture of the pleural cavity (thoracentesis) is sometimes followed immediately by fainting or collapse of the subject and may prove fatal. This so-called pleural shock has been attributed to e.g. air embolism but is most likely due to a pleural reflex which brings about cardiac slowing and a fall in blood pressure, being in this respect similar in character to the carotid sinus reflex (p. 241).

² As a result of the obstruction to breathing offered by the apparatus, these values are somewhat greater than actually exist during normal breathing.

INTRAPLEURAL (INTRATHORACIC) PRESSURES.

It has already been mentioned that the pressure on the pleural surfaces of the lungs is less than that upon their alveolar surfaces, i.e., the intrapleural pressure is subatmospheric. We must now consider the manner in which this "negative" pressure is produced. As stated above (p. 296) when the chest cavity is first expanded, the lungs are carried outwards by the inflow of air to fill the enlarged space.³ If this were all that occurred, the pressure within the lung and in the pleural cavity would be equalized and in the expanded position of the thorax after birth, as in the unexpanded state in the unborn animal, the pressure in the pleural cavity would not be subatmospheric. (The expansion of the thorax, however, and the consequent inflation of the lungs puts the pulmonary tissue upon the stretch.) In other words, the closed thoracic box, as a result of the first breath, becomes too large for the lungs to fill by a simple unfolding and distention of the walls of the air spaces. (The elastic tissue of the bronchial tree, blood vessels and of the air sacs themselves is put under stress and is constantly pulling against the stretching force.) This pull or recoil of the elastic lung amounts, in the adult when the chest is about midway between inspiration and expiration, to a pressure of from -4 to -5 mm. of mercury. The existence of such a pressure can be demonstrated indirectly by connecting a manometer with the trachea of a dead subject and puncturing the chest wall. Thus the negative pressure in the pleural cavity is abolished and the lungs are permitted to recoil, i.e., to collapse. Air is expelled from the alveoli and the manometer registers a pressure of $+4$ mm. Hg. This represents the pull which had been exerted before the puncture was made and is just equal in amount to the negative (suction) pressure in the pleural cavity. In the new-born the lungs fill the thoracic cavity with comparatively little stretching. The distention of the lungs increases, however, in later years since the thoracic cage grows more rapidly than the lungs; the elastic pull in consequence also increases and with it the intrapleural negative pressure. If, in the foregoing experiment, the lungs are distended maximally before the thoracic puncture is made, i.e., if they are fully stretched, then the pulmonary recoil causes a rise of 30 mm. Hg or so in the manometer column. The intrapleural pressure may be demonstrated

³ Some investigators believe that the normal lung is expanded in large part by "hydraulic traction" exerted on the visceral layer of the pleura by the parietal pleura and thoracic walls when these move outwards in inspiration.

FIG. 131. Model to illustrate the manner by which changes in thoracic capacity cause corresponding changes in the volume of air in the lungs and affect the return of blood to the heart. The large glass chamber represents the thorax; it is hermetically sealed and has a flexible bottom or diaphragm. The Y-tube, which is in communication with the atmosphere, represents the trachea and bronchi; the lungs are represented by the attached balloons composed of thin rubber. The pressure within the chamber, i.e., surrounding the balloons, is subatmospheric to start with; the balloons are therefore partially expanded. When the diaphragm is drawn down (as indicated by the dotted lines) the pressure within the chamber is further reduced. The rubber balloons are distended to a corresponding extent by atmospheric air entering through the Y-tube. As the diaphragm is allowed to rise again, the "negative" pressure within the chamber returns to its previous value and the elastic balloons recoil to their original dimensions.

The bottle shown in the lower left-hand part of the drawing contains fluid upon which pressure can be exerted to cause a steady flow up the tubing into the small oval chamber within the larger one. The oval chamber may be taken to represent the heart; the tubing connecting it with the pressure bottle represents the large veins, and the tubing leading from its right side the arteries. If the tubing on the left, as well as the upper part of the oval chamber (which corresponds to the auricles) be composed of some thin resilient material, then during the inspiratory reduction in intrathoracic pressure they will undergo expansion (dotted lines). A greater body of fluid will in consequence be transferred from the bottle to the small chamber representing the heart (see p. 138).

The manometer inserted into the wall of the large chamber registers the pressure changes (indicated by dotted lines) occurring during the descent and ascent of the flexible diaphragm.

directly by plunging a cannula connected with a manometer into the pleural cavity in such a way as to prevent leakage between it and the margins of the puncture. The manometer registers a negative pressure equivalent in amount to the positive pressure recorded in the previous experiment. In other words, the mercury is "sucked" toward the pleural cavity until the pressure within the latter just equalizes that of the atmosphere.

The intrapleural pressure (and the pressure throughout the thoracic cavity generally) is always subatmospheric under ordinary circumstances,⁴ and even after death. (This "negative" pressure is increased during inspiration—since then the distention of the elastic lungs is greater—and reduced during expiration.) During the former phase of quiet respiration (human) it amounts to about -6 mm. Hg, during an ordinary expiration it is about -2.5 mm. Hg. In the midposition as stated above it is about -4.5 mm. Hg. When the movements are forced it may be very greatly increased or diminished in the respective respiratory phase. During a strong inspiratory effort with the closed glottis it may amount to -40 mm. Hg and in forced expiration under the same circumstances it is abolished and a positive pressure of 50 mm. Hg or so substituted. These changes in intrathoracic pressure exert an influence upon other thoracic structures. An increase in the "negative" pressure causes the thin-walled veins and auricles to expand and fill with blood drawn from extrathoracic regions (fig. 131). On the other hand, in forced expiration against the closed air passages the thoracic walls press powerfully upon the air-filled lungs. The rise in pressure which results is transmitted to structures lying in the mediastinum. Blood is thus expelled from the large intrathoracic veins and auricles into the veins of the abdomen and neck.

THE RESPIRATORY MOVEMENTS

What has been said in the foregoing paragraphs should have made it clear that the flow of air into and from the lungs depends entirely upon changes in the capacity of the thoracic cavity. The lungs play a purely passive rôle. The air is not drawn in and expelled by active dilatation and contraction of the pulmonary passages, as was the belief at one time. Air is drawn in or forced out strictly

in accordance with the pressure differences between the atmosphere and the lung air caused by the expansion or contraction of the thoracic boundaries, i.e., as air is drawn into and expelled from a bellows. The principles are well illustrated by the model shown in figure 131. We will now consider how these changes are brought about.

The respiratory movements of an adult person occur normally at the rate of from 16 to 18 double excursions (inspiration and expiration) per minute. In the new-born infant during quiet breathing the rate is between 30 and 40 per minute.

(During inspiration the thoracic cavity is enlarged in all diameters, vertical, anteroposterior and transverse.) The enlargement, however, is not equal in all directions (p. 300). (The upper part of the thorax increases much less in capacity than does the lower; and since the position of the spinal column remains relatively fixed the increase in the anteroposterior diameter of the thorax is due mainly to an expansion forwards. The increase in the vertical diameter is due, not to an upward expansion of the chest cavity but to the downward elongation resulting from the descent of the diaphragm.)

Unequal enlargement of the thoracic box entails unequal expansion of the lungs. The lung is not distended equally from a center as in the inflation of an elastic-walled globe. Keith distinguishes (three zones in the expanding lung.

(a) A non-expansile *root zone* containing the bronchus, pulmonary vessels and lymphatics and their main divisions.

(b) An *intermediate zone* in which the vascular and bronchial branches radiate outwards toward the lung surface. Between these rays lies expansile pulmonary tissue. This zone therefore consists of tissue of varying degrees of expansibility, that lying near the periphery of the rays being more expansile than that situated more centrally.

(c) An *outer* or *subpleural zone* from 1 to 1½ inches deep of maximal distensibility.)

Those regions of the lung lying in relation to the relatively immobile regions of the thoracic walls, namely (a) the dorsal surface of the lung apex, (b) the posterior surfaces of the lungs in contact with the spinal column and attached segments of the ribs, and (c) the mediastinal surface lying in relation to the pericardium and other structures of the mediastinum, are expanded *indirectly*. The parts of the lung which are *directly* expanded during inspiration are those lying in contact with the freely movable boundaries of the thorax,

⁴ The intrapleural pressure may be measured in the human subject by inserting a hollow needle into the pleural cavity, injecting a small quantity (40 cc. or so) of air and connecting the needle with a water manometer and a recording system.

namely (a) the sternum and ribs and (b) the diaphragm.

It is evident that those portions of lung in contact with practically stationary regions of the thoracic walls can only be expanded indirectly, that is, when other parts of the lung move out of the way. This could not occur did the root of the lung remain fixed. As a matter of fact the lung root moves downwards, forwards and laterally during inspiration (fig. 132) and, as shown by Macklin by X-ray studies upon human subjects, the bronchial tree becomes elongated (stretched)

FIG. 132. Mediastinal aspect of the right lung to show the respiratory movement of the lung root. The crus of the diaphragm is also indicated, and its attachment to the root of the lung through the pericardium. The arrows indicate the direction of the inspiratory movement of the various parts of the lung. (After Keith.)

during the inspiratory phase. The trachea becomes stretched and the apex of the lung actually descends as it expands. During expiration the highly elastic bronchial tree recoils to its previous length and the lung root ascends (fig. 133). If the root of the lung were fixed, little expansion of a region such as the apex or of other regions classed as expanding indirectly could result. Nor could anything but a very moderate expansion of other regions (e.g., costosternal and diaphragmatic, etc.) occur if the bronchial tree were unable to lengthen. It is the *elongation* of the rays as described above rather than the widening of the spaces between them at their original lengths,

i.e., like the separation of the sticks of a fan, that is of importance in permitting the expansion of the intervening pulmonary tissue.

The effect of the enlargement of the thorax is exerted first and to the greatest extent upon the lung tissue in relation to the movable parts of the chest walls. The inspiratory decrease of intrapleural pressure in the diaphragmatic regions of the

FIG. 133. X-ray photographs (retouched) of the bronchial tree of a young woman: A, in full expiration; B, in full inspiration. (After Macklin.)

thorax is considerably greater than that in the region of the apex or in other parts of the lung which are expanded indirectly. As a result of the greater negative pressure in the lower part of the thorax a horizontal groove is sometimes developed here (Harrison's sulcus) when the framework, as in rickets, is soft and yielding. The restricted expansion of the air sacs of the apex and other regions of the lung which are expanded indirectly has been held responsible for their being so commonly the primary site of tuberculous infection.

THE ENLARGEMENT OF THE THORACIC CAVITY DURING INSPIRATION

This is effected, according to Keith, by four distinct mechanisms which consist of the movements of:

(a) The *thoracic lid* or *operculum* (1st rib and manubrium sterni).

FIG. 134. Diagram to show the respiratory movements of the first pair of ribs and manubrium sterni, and the effect of these movements on the expansion of the apex of the lung. (After Keith.)

FIG. 135. Diagram to illustrate the action of the external intercostal muscles (E.I.) during inspiration; EXP., expiration; INSP., inspiration.

(b) The *upper costal series* (2nd to 5th ribs inclusive).

(c) The *lower costal series* (6th to 10th ribs inclusive) and the *diaphragm*.

(d) The *floating rib series* and the *muscles* of the abdominal wall.

(a) *The thoracic lid or operculum*

The thoracic lid or operculum is formed by the first pair of ribs and the manubrium sterni. It is

jointed behind to the spinal column and in front to the sternum by the manubrio-sternal joint. During the elevation of the thorax in inspiration the thoracic lid moves as a single piece upon the body of the sternum, assuming a more horizontal position (by from 1° to 16°). That is, the manubrium is pushed upward and forward (fig. 134). Thus, the upper part of the thorax is increased in its anteroposterior diameter. The anterior portion of the lung apex is directly expanded to some extent by this mechanism. The extent of the movement of the thoracic lid varies considerably

FIG. 136. A diagram showing the axis of movement (AB and CD) of the ribs from the 2nd to the 6th. The ribs from the 7th to the 10th also make a movement around an antero-posterior axis but not around the axis CD. The interrupted lines indicate the position of the rib in inspiration. (After Gray.)

in different individuals and with the depth of inspiration. It is very slight in quiet breathing. The manubrio-sternal joint becomes ankylosed in later life but rarely before the 60th year.

(b) *The upper costal series*

The 2nd, 3rd, 4th, 5th and 6th ribs slope obliquely from behind downwards and forwards. Each rib is longer, its direction more oblique and it makes a fuller sweep outwards than its neighbor immediately above. During inspiration these ribs (with the exception of the 2nd) assume a more horizontal position, their anterior portions moving upward and forward. That is, each rib rotates around an oblique horizontal axis parallel to its neck (fig. 136CD). The sternum is thrust for

ward and upward, executing a movement of the manubrio-sternal joint. These movements increase the anteroposterior diameter of the thorax. The elevation of the ribs is effected by the external intercostal muscles. The muscle fibers pass obliquely downwards and forwards from the lower border of one rib to the upper border of the rib below. When the muscle contracts it exerts a pull upon these attachments which tends to depress the upper rib of the pair and to raise the lower.

receive impulses alternately along the intercostal nerves.

The strongly bowed mid-portion of the body of each rib from the 2nd to the 6th also becomes elevated, in relation to its two ends, rotating around an oblique anteroposterior axis. This movement which is compared to the raising of a bucket-handle to a more horizontal position increases the transverse thoracic diameter (fig. 136AB).

FIG. 137. Upper, radiogram showing the position of the diaphragm during expiration and inspiration. Note the effect upon the position and shape of the heart. (After Norris and Landis.) Lower, diagram showing the expiratory and inspiratory positions of the diaphragm.

The first rib, however, acts through the contraction of the scalene muscles, as a fixed point above, so that contraction of the external intercostals can only result in an elevation of the ribs. Owing also to the obliquity of the fibers which are attached below to the anterior end of the long arm of a lever and above to the posterior end of the long arm, a distinct mechanical advantage is given to the upward movement (fig. 135). The internal intercostal muscles are, in the cat at any rate, as shown by Bronk and Ferguson, expiratory in function. The internal and external intercostals

(c) The lower costal series and the diaphragm

The ribs from the 7th to the 10th also swing outwards and upwards (bucket-handle movement) during inspiration, rotating around an oblique antero-posterior axis which passes through the mid-line in front and the rib necks behind. The subcostal angle is widened by this movement and the transverse diameter of the lower part of the thorax increased; the antero-posterior diameter is slightly reduced.

The diaphragm is the chief muscle of respiration, its movements being responsible during deep

breathing for 60 per cent of the total amount of air breathed. It consists of a musculo-tendinous sheet arched toward the thoracic cavity. The tendinous portion is centrally placed (central tendon) and attached to the pericardium. The muscular tissue is placed circumferentially. (The diaphragm consists of two parts which differ from one another in their actions.

(a) The *costosternal* part arises from the back of the xiphoid and the cartilages and adjacent portions of the six lower pairs of ribs. It is attached to the anterior edge of the central tendon.

(b) The *lumbar* or *crural* part arises from the fibrous arches over the quadratus lumborum and psoas muscles and by two fleshy bundles (the crura of the diaphragm) from the bodies of the upper lumbar vertebrae. The fibers so originating are inserted into the posterior margin of the central tendon.

ACTION OF THE DIAPHRAGM. (The diaphragm descends during inspiration and ascends during expiration. In full expiration its upper limit lies at a level situated between the costal cartilages of the 4th and 5th ribs.) In quiet breathing the range of its movement is about 1.2 cm. and in forced breathing about 3.0 cm. The total diaphragmatic surface is about 270 sq. cm. A descent of 1.0 cm. therefore (assuming that all regions descend practically to the same extent) will increase the thoracic capacity by 270 cu. cm. and cause a corresponding volume of air to enter the lungs.

As the diaphragm descends its domed shape alters very little; it may be seen by means of the fluoroscope to move up and down like a piston (fig. 137). At the end of expiration a considerable proportion of the diaphragmatic surface is in contact with the chest wall as high as the 6th or 7th rib, but during inspiration it is "peeled off" the thoracic boundary, while the base of the lung expands to fill the space (pleural sinus). As a result of the slight indrawing of the intercostal spaces caused by this movement, a faint shadow may be seen to move down the side of the chest wall in most normal persons. This is known as Litten's sign. The *costosternal* part of the diaphragm, using the lower ribs, which through the action of the external intercostals serve as fixed points, moves downward and forward pushing the abdominal viscera before it. Thus, the capacity of the lower part of the thorax is increased. The abdominal wall distends but when, as a result of the resistance offered by the abdominal muscles, the downward movement of the viscera becomes arrested these act as a fixed point for the continu-

ing contraction of this part of the diaphragm. Its force is now spent in raising the lower ribs to which it is attached; through this action the sternum is thrust forward and upward. The *spinal* or *crural* part in its descent acts solely in increasing the vertical diameter of the thorax.

The excursions of the diaphragm and consequently its mid-position are influenced by (a) the upward pull of the subatmospheric intra-thoracic pressure, and (b) the abdominal viscera. In the standing position the weight of the latter exerts a downward pull and so aids the descent of the diaphragm but hinders its ascent; the mean or mid-position of the diaphragm is therefore taken up at a lower level than in recumbency when the viscera exert an upward pressure. (c) The abdominal muscles: these, when lax and the body in the standing position, allow the viscera to subside to a lower level and so to increase the downward pull upon the diaphragm. In persons with extremely weak abdominal muscles, such as subjects of visceroptosis, the downward pull upon the diaphragm greatly interferes with its movements. The breathing is then largely costal.

(d) *The floating ribs (11th and 12th) and the abdominal muscles*

Functionally the floating ribs must be considered with the abdominal muscles which are the antagonists of the diaphragm. The recti and oblique muscles relax as the diaphragm descends; they contract with its ascent.

EXPIRATION

(Expiration is to a large extent a passive movement; in quiet breathing it is probably entirely so. That is, the contraction of the inspiratory muscles ceases; the thoracic framework tends through its own weight to resume its former position, the elastic lungs recoil and the relaxed diaphragm is drawn upwards toward the thoracic cavity by the "negative" intrathoracic pressure which is greatest at the end of inspiration. There is, however, also a definitely active element in a forced expiratory movement. As mentioned above, the abdominal muscles contract and by pressing upon the viscera aid the ascent of the diaphragm, i.e., the diaphragm is "pushed" up by the increased intra-abdominal pressure resulting from the contraction of the abdominal muscles, as well as "sucked" up by the subatmospheric pressure within the thorax.

During forced expiration the internal intercostals whose fibers like those of the external intercostals course obliquely but in the opposite direction

downwards and backwards) contract and so aid in the depression of the ribs. The restoration of the thorax to its previous diameters is, of course, accompanied by a corresponding reduction in the capacity of the lungs and the expulsion of air from its air spaces.

MOVEMENTS OF THE BRONCHIAL TREE DURING RESPIRATION. In addition to the inspiratory elongation of the bronchial tree mentioned above, the bronchioles and smaller bronchi dilate during inspiration and constrict during expiration. The rhythmical bronchial movements appear, from the studies of Ellis and of Nicholson, to be purely passive in nature and not integrated through reflex mechanisms with inflation and deflation of the lungs. The bronchioles also exhibit a peristaltic movement which can be detected by X-ray photographs of the bronchioles after the injection of lipiodol⁵ or other material which is opaque to the X-ray. It is not thought that the peristaltic movement plays any part in the movement of air, but it appears to assist in the movement of foreign material towards the large air tubes. This bronchiolar peristalsis is said to be increased in lung abscess and diminished in bronchiectasis. It is decreased by morphine.

PULMONIC ALVEOLAR VENTS. The existence of certain pores in the alveoli (pores of Kohn) have long been recognized, but the difficulty of being certain that they are not artefacts produced by the method of preparing the sections has prevented their wide acceptance as normal structures. Quite recently, however, Macklin has been able to demonstrate the presence of such vents in thick sections prepared from the lungs of many species including man. Examination of the sections justifies the belief that they are normal communications between the alveoli. While the function of the vents is not as yet completely understood, it appears probable that they play a significant part in the equalization of pressures in groups of the alveoli, particularly perhaps during forced inspiration. The vents are opened wide during inspiration and may be entirely closed in expiration. The rôle of these passages in the spread of infection will doubtless receive serious consideration.

COLLATERAL RESPIRATION. This phenomenon (Van Allen, Lindskog and Richter) depends on the fact that the lobular divisions of the bronchial tree of any one pulmonary lobe are interconnected. Air may pass from one alveolus to an adjoining one presumably through the alveolar vents but possibly also by rapid diffusion. This communication may be demonstrated when a bronchus supplying one lobule is obstructed, for it is then found that the alveoli of the obstructed

lobule may be well ventilated for prolonged periods. Collateral respiration is prevented by inflammatory exudates or secretions or in circumstances in which the alveolar walls are not adequately distended. In this latter case the vents may not be open. In species in which the interlobular septa are complete as in man there is no provision for collateral respiration between different lobules. Experimental evidence has been obtained which indicates that atelectasis of a lobule does not develop after obstruction of its bronchus. Conversely, re-aeration of an atelectatic lobule may take place by this collateral route. It would thus appear that considerable anatomical and physiological evidence has been obtained for a peripheral mechanism which has as its objective the adequate and uniform but not excessive distension of the pulmonary alveoli.

EXPULSION OF FOREIGN MATERIAL—THE ACT OF COUGHING. There are three mechanisms for the expulsion of foreign material. First, the action of the cilia, p. 293; second, the peristaltic motion in the bronchioles; and third, the cough reflex. The peristaltic movement has been referred to above. The cough reflex is most commonly initiated by the stimulation of afferent nerve endings in the region of the tracheal bifurcation, the most sensitive area, or in the laryngeal mucosa. It may also be initiated from the excitation of vagal afferents in the lungs, or from nerve endings in the pleura. Ear disease, through the stimulation of terminals of the auricular branch of the vagus (Arnold's nerve), may also cause coughing. The act itself consists of a short inspiration followed immediately by closure of the glottis and a forcible expiratory effort. A considerable degree of pressure is thereby developed within the lung. The glottis then opens suddenly and offending material is moved a variable distance along the air passage. If it reaches an insensitive area the coughing ceases. During the subsequent inspiration the irritating particle, if not large enough to seriously obstruct the air passage, remains during the subsequent inspiration in its new position, from which it is carried forward again during succeeding expulsive efforts until it is swept away from sensitive areas.

Hiccup or singultus is a spasmodic and purposeless contraction of the diaphragm which results from many causes or may occur without known cause; it occurs rarely in epidemic form. It is usually reflex in nature being initiated by some abnormal stimulation of the afferent nerve terminals in the diaphragm. The fibers of the phrenic nerve constitute the efferent limb of the reflex. In some instances, hiccup may be due to stimulation of the respiratory center itself by some agent

⁵ A preparation of iodized oil.

in the blood. Hiccup following abdominal operations may be most intractable and endanger the life of the patient. The inhalation of an air mixture containing 6 or 7 per cent of carbon dioxide (or simply breathing and rebreathing from a bag for a number of respirations) has been reported to be a valuable means of terminating an attack.

Artificial Respiration

Schafer's prone pressure method is the best known and most widely practised means of artificially ventilating the lungs when spontaneous respiration has failed. It has the advantage that it requires no special equipment and can be undertaken by one person. The operator kneels astride the subject stretched prone beneath him and with the palms of his hands upon the subject's lower ribs leans forward and exerts gentle but

expand the chest. The arms are returned to the ground during the expiratory phase. In the rocking method the inspiratory and expiratory movements of the diaphragm are brought about by the weight of the abdominal viscera. The subject is placed prone upon a stretcher which is then rocked on a trestle around a transverse axis. The tilt of the body both in the head-down and feet-down positions is from 45 to 50 degrees. Ten double movements are made per minute. This method is also believed to encourage the circulation of blood through the coronary and cerebral vessels and thus to sustain the vitality of the myocardium and nervous centers.

During the last few years several methods have been developed for the long continued application of artificial respiration by various mechanical processes. This work was begun by Thunberg

FIG. 138. The Drinker respirator. 1, pumps; 2, motor; 3, vents; 4, alternate; 5, valves; 6, manometers; 7, external shutters; 8, adjustment for head rest; 9, adjustable ring to hold collar in place. (After Shaw and Drinker, *Jour. Clin. Investig.* 1930/8/33.)

firm pressure for 2 seconds. He then straightens up and releases the pressure for 2 seconds. These alternating movements are repeated at the rate of normal respiration. The downward and forward movement compresses the thorax and pushes the diaphragm upward, thus expelling air from the lungs. The recoil of the thorax to the resting position follows the release of the pressure, and thus induces artificial inspiration. It has been found, however, from experiment that this method does not provide sufficient pulmonary ventilation in an animal whose respiratory muscles have been paralyzed by curare (Meltzer). Much more adequate aeration of the lungs is claimed for the Neilson-Schafer (Drinker) method and for Eve's rocking method. In the former procedure the extended arms of the subject are raised above his head by a second operator during the inspiratory phase of "Schafer respiration." This helps to

in Lund who devised an apparatus called the barospirator. The subject was placed inside a metal chamber in which the pressure was raised and lowered rhythmically by means of the stroke of a very large piston. The interchange of air within the lungs was caused by a rise and fall of pressure of the air in the external atmosphere. This apparatus was effective and a model was built large enough to accommodate patient, nurse and doctor. All three were ventilated without movement of the chest. A certain amount of discomfort was experienced in this cabinet due to the change in pressure on the two sides of the eardrum during the increase and decrease of air pressure. A more generally applicable model was produced by Drinker at Harvard. In this type the patient's head remains outside the cabinet (fig. 138). The chest is expanded by reducing the pressure within the cabinet and as the pressure is

raised again, the natural elasticity of the lung causes expiration. Forced expiration, however, may be produced by raising the pressure above atmospheric. Patients have been adequately ventilated with this apparatus for many months. Some difficulty is occasionally encountered in the regulation of the rate and depth of respiration, but by determining the oxygen saturation of the arterial blood or watching for signs of cyanosis an observer can usually regulate the ventilation quite satisfactorily.

Two other types of apparatus should be mentioned; (1) the jacket model of Sahlin which operates like the Drinker machine but is applied only to the chest, and (2) the Bragg-Paul pulsator which consists of a hollow elastic bandage placed around the chest. The bandage, when inflated by an electrically driven bellows, compresses the chest, which returns to the mid-position by virtue of its own elasticity during the intervals between the compressions.

The object of artificial respiration is not only to aerate the lungs but also to stimulate the respiratory center. Due largely to the insistence of Yandell Henderson, carbon dioxide is now added, whenever possible, to the respired air which should contain from 40 to 50 per cent of oxygen. The high carbon dioxide tension combined with the rhythmical inflation and deflation of the lungs, which presumably cause the discharge of afferent impulses, encourage the return of spontaneous breathing.

PNEUMOTHORAX

Air may enter the pleural cavity through a penetrating wound of the chest (*open pneumothorax*), as a result of the rupture of an emphysematous vesicle on the surface of the lung or from the extension through the pleura of a lesion of the pulmonary tissue (e.g., tuberculous) or of some other air-containing organ such as the esophagus or stomach. When the intrapleural space contains air but communication with the atmosphere has become occluded the pneumothorax is said to be *closed*.

OPEN PNEUMOTHORAX

If the opening through the thoracic wall were large and the mediastinum acted as a more or less rigid partition the pleural cavity of the affected side could be considered quite separate from that of the sound side. The lung on the open side would exhibit its elastic properties and recoil; the reserve and residual airs (p. 308) would be expelled and the lung would be in the collapsed state. The

opposite lung would be unaffected. Actually, the mediastinum, as a rule, offers little resistance, so the two pleural cavities, though anatomically separate, act so far as the distribution of pressure is concerned, almost as if they were a single cavity. Consequently when an opening exists in the thoracic wall the yielding mediastinum with its contents—heart and great vessels—moves toward the sound side and the increased intrapleural pressure is transmitted to that side. The negative pressure on both sides of the chest is therefore reduced and both lungs tend to collapse, but, the pressure on the sound side is always altered less than the pressure on the side of the opening. Graham and his associates found in experiments upon the human cadaver and upon the living dog that an air pressure of +10 cm. of water created in one pleural cavity, caused the pressure in the opposite pleural cavity to rise to between +7 and +8 cm. With the introduction of higher pressure a greater difference was found between the two sides. For example, when a pressure of 48 cm. of water was created in one pleural cavity the pressure on the opposite side was less than 21 cm.

Other things being equal the size of the opening in the chest determines the extent to which the negative pressure becomes reduced. If the chest were immobile and the mediastinum quite unresisting this factor would exert no influence upon the pressure ultimately attained within the thorax. The pressure would finally become atmospheric throughout and complete collapse of both lungs would result. But in the living body the response to pneumothorax is to deepen the respirations. That is, the thorax enlarges and the lungs expand to a greater degree to maintain the negative pressure despite the communication between the chest cavity and the atmosphere. It therefore becomes a matter of competition between the amount of air entering the lungs through the trachea and that entering through the opening in the chest during inspiration. The chest may be compared to a bellows with a hole in its wall; when the bellows is opened (inspiration) the volume of air entering through the leak and that through the nozzle (which is analogous to the trachea) will depend upon the sizes of the respective openings. From this it will be realized that with quite a small opening an intrapleural pressure of practically normal value could be maintained. Even with a very large opening—one exceeding in extent by several inches the cross area of the trachea—though the intrapleural pressure could not be maintained at its normal value and partial collapse of the

lungs would result, nevertheless, a normal volume of air could be drawn in during inspiration. The reason for this is, of course, that the amount of air required for ordinary existence—tidal air—is only a small fraction of the vital capacity. In other words a partially collapsed lung is adequate for ordinary needs. When, however, the opening is so large that the thorax, even when maximally enlarged, cannot expand the lung sufficiently to maintain the tidal air at its normal value, dyspnea and cyanosis will result and the patient will die. It also follows that a patient whose vital capacity is already reduced by disease cannot survive with an opening as large as that which can be tolerated by a person possessing a larger vital capacity. As a result of the work of Graham and his associates the following summary may be made.

FIG. 130. Bronchiectasis. X-ray photograph after injection of bronchial tree with lipiodol. (After Moll, retouched.)

(a) Both lungs are affected in a pneumothorax. If the opening is small or if in a closed pneumothorax the pressure is low, the effect upon the two lungs is nearly equal.

(b) A bilateral open pneumothorax is not fatal unless the openings are large.

(c) The size of the opening compatible with life bears a relation to the vital capacity of the subject. Any pneumothorax, unless the opening is very small, would be fatal to a person who before the pneumothorax occurred had possessed a vital capacity little greater than his tidal air. It is therefore possible to perform an intrathoracic operation upon a subject possessing a high vital capacity without distending the lungs by the delivery of air under pressure through the trachea.

(d) The reduction in the intrathoracic "negative" pressure caused by a pneumothorax tends to impede the filling of the right heart and to produce stasis in the venous system (p. 138).

(e) Open pneumothorax increases the heat loss of the body. In dogs the body temperature usually falls 2°C. half an hour after an opening has been made in the chest. After closure the temperature rises again and within an hour has nearly reached the normal level.

When the mediastinum has been rendered solid and resistant by previous disease some of the foregoing statements obviously will not apply. All if the pleural surfaces on the side of the opening are adherent and so hold the lung out against the thoracic wall a pneumothorax will not result. If, as a result of such adhesions the pneumothorax is limited in extent, only a part of the lung is affected.

COLLAPSE OF THE LUNG, ARTIFICIALLY INDUCED. Pulmonary collapse is induced as a therapeutic measure in certain pulmonary lesions, especially tuberculosis, in which the disease is mainly confined to one lung. The operations employed are (a) *pneumothorax*, (b) *phrenic avulsion*, (c) *thoracoplasty*. The aim is to render lung functionless and so to place it at rest. Healing is thereby promoted. Benefits also result from obliteration of the vessels of the diseased lung. Blood is diverted from the poorly aerated tissue to healthy lung, whose capillary bed becomes enlarged for the accommodation of the blood. Anoxia and other effects are thereby relieved (see p. 364). (a) *Pneumothorax*. The pneumothorax is of the closed type, air is introduced into the pleural cavity under pressure. The injected air after a time becomes absorbed (see atelectasis, p. 370) and the operation must be repeated in order to maintain the lung in the collapsed state. This operation or phrenic avulsion (below) is employed in the comparatively early stages of pulmonary tuberculosis. (b) *Phrenic avulsion*. One or other phrenic nerve is exposed in the neck and sectioned. The lower segment is then seized with forceps and pulled until it gives way, a considerable section of the nerve being removed. The corresponding half of the diaphragm is paralyzed. The latter ascends into the thoracic cavity where it remains fixed at a high level. The capacity of that side of the thorax is reduced, the lung collapsed to a corresponding degree. A section of the phrenic in the neck is ineffective as a means of paralyzing the diaphragm since fibers of the 5th cervical nerve (accessory phrenic) join the main trunk of the nerve within the thorax.* (c) *Paravertebral thoracoplasty*. This operation is performed in advanced cases with cavity formation and when pleurae are adherent and consequently an artificial pneumothorax is not feasible. From 1 to 6 inches

* As a matter of fact simply crushing the nerve is often resorted to in order to reduce the mobility of the affected lung for a time. Regeneration of the nerve occurs after a year or so.

the upper nine or ten ribs are removed from the back of the thorax. The chest wall thus rendered plastic contracts inwards and compresses the corresponding lung.

Pleural shock. Marked slowing of the pulse and a profound fall in blood pressure, which may lead to fatal syncope, sometimes follows puncture of the chest wall for the withdrawal of fluid or during the production of pneumothorax. The cardio-vascular reaction is apparently due to a pleural reflex since a similar effect upon heart rate and blood pressure can be induced in animals by stimulating the pleura. It is more commonly seen when the chest is punctured for the withdrawal of fluid than during the injection of air for the production of pneumothorax, a fact among others which argues against its being due to air embolism (footnote, p. 142). Injury to the visceral pleura or to the underlying layer of pulmonary tissue appears to be a factor essential for the production of this type of circulatory collapse.

BRONCHIECTASIS

This is the term applied to an abnormal dilatation of the bronchi or bronchioles. The dilatation may be localized or widespread, fusiform, irregular, beaded or uniform in distribution. The contour of the bronchial tubes is readily demonstrated by X-ray after the injection of lipiodol (fig. 139). Secretion may collect within the dilated lumen and be expectorated at intervals as large quantities of a foul-smelling sputum. This classical sign of the condition is only seen in its advanced stages. More commonly the sputum is small in amount and in the form of yellow "chunky" pieces (Warner).

Causation

Bronchiectasis is practically always secondary to some other affection of the lungs. The primary change leading to the condition is weakening of the bronchial wall as a result of infective processes. The elastic and muscular tissues are

atrophic. As we have seen (p. 303) the bronchial tree dilates during inspiration and contracts during expiration. The latter movement is, in part at least, an elastic recoil. With the gradual deterioration of the elastic tissue of the bronchial wall, the latter's resiliency becomes progressively less. The lumen of the tube does not regain its normal caliber after inspiration but remains more or less dilated. Dilatation beyond this is due to the fact that during inspiration the pressure within the bronchial lumen is greater than the pressure within the extrabronchial tissues and throughout the thoracic cavity generally. During expiration, however, the intrabronchial pressure cannot rise above the pressure in the surrounding tissue; the bronchial walls are supported. Coughing or other conditions causing a general rise in intrapleural pressure cannot, therefore, induce bronchiectasis. On the other hand conditions which increase the negative pressure within the thorax, such as the collapse of a lobe (lobar atelectasis) as a result of a bronchial occlusion or of an entire lung (massive atelectasis) (p. 370), will obviously increase the tendency to bronchiectasis. Lobar atelectases were found in 6 per cent of cases of bronchiectasis observed by Warner and Graham. Incomplete obstruction of a bronchus especially if it exerts a valve-like action, by permitting inspiration but hindering expiration, favors the development of bronchiectasis (see also p. 369). The latter is therefore not an uncommon result of the lodgment of a foreign body in a bronchus.

Fibrosis of a lung or portion of lung is considered by some as a potent cause of bronchial dilatation. It is thought that the fibrosing lung as it shrinks makes equal circumferential traction upon the bronchi or bronchioles and thus leads to their dilatation. It is probable that even in these instances previous weakening of the bronchial wall is the primary fault since bronchiectasis commonly occurs in the absence of fibrosis.

CHAPTER XXX

THE AIR OF THE LUNGS

The quantity of air drawn into and expelled from the lungs in quiet respiration is only a fraction ($\frac{1}{3}$ or so) of that which can be inhaled and exhaled during deep breathing. The air which passes in and out during ordinary respiration is spoken of as the tidal air. It amounts on an average to 500 cc. The average man after he has completed an ordinary expiration, can inhale, by making the deepest inspiration of which he is capable, about 3000 cc.¹ This is termed the *complemental air*. If, starting again from a position of rest, i.e., at the end of an ordinary expiration, a forcible expiratory effort is made, about 1000 cc. can be expelled. This is called the *supplemental air*. Since in ordinary breathing the lungs must hold this extra quantity of air which can be expelled upon demand it was called the *reserve air* by Hutchinson. The volumes of the complemental and supplemental airs, i.e., the total amount of air which can be exhaled after a maximal inspiration, is called the *vital capacity*. Thus, in round figures,

Tidal air.....	500 cc.
Complemental air (including tidal air).....	3000 cc.
Supplemental (reserve) air.....	1000 cc.
Vital capacity.....	4000 cc. ²

(see fig. 140).

Even after the most strenuous expiratory effort a large quantity of air still remains in the lungs, since collapse of the air cells cannot occur so long as the intrathoracic pressure remains negative (subatmospheric). This is termed the *residual air*. It is present in the lungs after death but is expelled in large part when the pleural cavity is opened and the pressure upon the two sides of the lung becomes equalized. The residual air amounts to from 1000 to 1500 cc. but it shows considerable individual variation.

When the lungs collapse as a result of opening the chest, the small amount of air which still remains entrapped within the air sacs and cannot

be expelled by ordinary means is known as the *minimal air*. The minimal air is responsible for the characteristic buoyancy of pulmonary tissue. The lungs of a dead animal float in water and for this reason are popularly known as the "lights." The fact is important in medico-legal practice and is applied as a test to determine whether an infant was still-born or had died after having once breathed.

Further partitions of the lung are distinguished by clinicians. Thus *total lung capacity* is the vital capacity plus the residual air, that is, the total volume of air which the lung can hold after a maximal inspiration. It amounts to about 5000 cc. The *minute volume* is the total volume of air breathed per minute, i.e., the volume of the tidal air multiplied by the number of respirations per minute.

The *functional residual air* is the amount of air remaining in the lungs at the end of a normal expiration, that is, the supplemental or reserve air plus the residual air.

THE VITAL CAPACITY (V.C.) AND ITS VARIATIONS

A relationship between certain body measurements and vital capacity has been shown by several investigators. Hutchinson, a pioneer in the field, invented the spirometer and studied the vital capacity in a large number of individuals, normal and diseased. He demonstrated the relation of vital capacity to height and weight.³

³ Dreyer investigated the vital capacity in a number of healthy individuals and demonstrated a relationship between it and "stem length" (height of body from chair in sitting position) weight, and body surface respectively.

For the average healthy person the relationship between vital capacity and weight is shown in the formula:

$$\frac{W^n}{V.C.} = K$$

When W = weight of body in grams; power n = 0.72; V.C. = vital capacity in cubic centimeters; K = a constant having a value of 0.690. The normal standard for a given weight is calculated as follows:

$$\frac{W^{0.72}}{0.690} = V.C. \text{ in cubic centimeters}$$

¹ This of course includes the tidal air. Some take the volume which can be inspired after a normal inspiration as the complemental air. It then does not include the volume of the tidal air.

² The values vary considerably between individuals. Those in the table are for a healthy adult male of average build.

The most consistent relationship, as shown by Dreyer and by West, exists between vital capacity and surface area (see table below).

A fairly close relationship between total height and vital capacity was also found, the latter expressed as cubic centimeters being 25 times the height in centimeters for men, 20 times for women and 29 times for athletes. For example, an average adult male 170 cm. tall would have a vital capacity of $(170 \times 25 =)$ 4250 cc. The surface area of the same individual assuming an average weight for his height, namely, 70 kgm., would be 1.80 square meters. Therefore his vital capacity should be $(1.80 \times 2500 =)$ 4500 cc. The difference in the results of the two methods of calcula-

sedentary work being considerably lower than those pursuing more arduous occupations. Dreyer divided his subjects into three classes A, B and C. Class A are those with the maximum vital capacities. Classes B and C have values 90 per cent and 85 per cent respectively of those of Class A. He considers a reduction of 15 per cent below the standard of the class to which the subject belongs as an almost certain indication of some abnormality. It should be mentioned that measurements of chest expansion, as by means of a tape measure may bear little relation to the vital capacity. A subject with powerful muscles can enlarge his thoracic cage to a capacity greater than his lungs are able to fill. His diaphragm

FIG. 140. Showing subdivisions of lung air. (Modified from Christie.)

tion of the normal standard is therefore around 5 per cent.

The ratios of vital capacity to height and surface area respectively, as found by West, are shown in the following table:

	Men	Women	Athletes
Vital capacity, cc. per cm. height.	25.0	20.0	29.0
Vital capacity, cc. per square meter of body surface.....	2500	2000	2800

Occupation as shown by Dreyer and others exerts a potent influence upon the vital capacity. The normal standard of persons employed in

The subject's vital capacity as directly measured by the spirometer is expressed as a percentage of the normal standard for age, sex and occupation.

instead of taking a full downward stroke is drawn upwards while the viscera are forced into the extra-thoracic space by a strong contraction of the abdominal muscles.

The vital capacity is reduced in many diseased conditions especially those involving the respiratory and vascular systems. Among these are

(a) Conditions which directly involve the lungs, e.g., pneumonia, pulmonary tuberculosis, emphysema, etc.

(b) Mechanical interference with the enlargement of the thoracic cavity, e.g., as by abdominal conditions impeding the movements of the diaphragm or abnormalities of the thoracic walls. The movements of the thoracic walls may be seriously restricted by abdominal or pleuritic pain.

(c) Intrathoracic conditions which encroach upon the space normally occupied by the lungs, e.g., pericardial or pleuritic effusions, pneumothorax, tumors, etc.

(d) Heart disease. Engorgement of the pulmonary vessels causes an encroachment upon the alveolar spaces and so reduces their capacity. Pulmonary edema involving especially the lung bases is a contributory factor in the reduction of the vital capacity in cardiac cases. Peabody found that when in heart disease the vital capacity reached 40 per cent of the normal, the subjects were almost constantly dyspneic or showed dyspnea upon the slightest exertion (p. 354).

The vital capacity, the functional residual air and the residual air and consequently the total lung capacity are reduced in the recumbent posture.

METHODS OF MEASUREMENT

It must be emphasized that any reduction of the vital capacity of an individual is of much greater significance than an apparently abnormal value encountered at the first examination. The vital capacity, the complementary air, or the reserve air can be readily measured in a simple spirometer. For the determination of residual air or the volume of the lung at any phase of respiration the modification of Humphrey Davy's dilution method described by Van Slyke and Binger is recommended. Oxygen to which a known volume of hydrogen has been added is breathed in and out from a spirometer. The carbon dioxide is absorbed by sodium hydroxide. A sample of the mixture is analysed and the ratio of N_2 to H_2 determined, since,

$$(1) \quad \frac{N_2 \text{ in sample}}{H_2 \text{ in sample}} = \frac{\text{Total volume } N_2}{\text{Total volume } H_2}$$

and (2) the total volume of H_2 being known, the total volume of N_2 in the lungs can be calculated; then in as much as nitrogen forms 79 per cent

$$\text{of the lung air, } \frac{\text{vol. } N_2}{79} \times 100 = \text{lung volume.}$$

ALVEOLAR AIR

This is the air contained in the air sacs and alveoli. Its gases come into equilibrium with those in the blood of the pulmonary capillaries. The alveolar air is being continually renewed through the to and fro effect of the respiratory movements. But since the lungs are not emptied during expiration it is quite clear that complete renewal of the air cannot be affected by a single respiration. The ventilation of the lungs occurs by the mechan-

ical mixing of the inspired air with the lung and by the slower process of diffusion. During expiration the air of the upper respiratory passage is first expelled; then follows a part of the air of the bronchial tree. At the end of expiration the air which has been in the distended alveoli, since they have been reduced in capacity, now overflows into the bronchioles and bronchi. At the next inspiration this air is swept back again into the air sacs its place being taken by fresh atmospheric air. The latter as compared with the alveolar air has a high oxygen pressure and a low pressure of carbon dioxide. Oxygen therefore diffuses from the inspired to the alveolar air and carbon dioxide passes from alveolar to inspired air. The mechanical mixing of the inspired air with the air already in the lungs occurs, chiefly, at the beginning

FIG. 141. Description in text.

FIG. 142. A shows a 'spike' of smoke moving through a glass tube. B shows the condition when the current is suddenly stopped and mixing occurs instantaneously. C shows clear air drawn in through a glass tube, showing how a column of smoke crosses a bulb with mixing or sweeping out of the air within it. (A. Yandell Henderson and associates.)

inspiration and the end of expiration. Mixing is also brought about through the convection currents set up by the entrance of the cooler atmospheric air.

The process by which the air in the alveoli is renewed may be made clear by the illustration in figure 141. A is a glass tube to which is attached a compressible bulb B. If the bulb be filled with smoke then compressed, the smoke will not be completely expelled by a single compression. A portion only issues from the end of the tubing. The rest will be in the compressed bulb and tubing. When the bulb is released again smoke will be drawn back into the bulb and the tubing will be filled with fresh air. The smoke in the tube will be diluted through mechanical mixing and diffusion. After a series of compressions the smoke would be completely cleared away. If the air were supplied steadily with smoke through the

and rhythmical compressions and decompressions the bulb maintained at a definite rate, a certain constant dilution of the smoke would result. The smoke entering the bulb may be taken to represent the carbon dioxide passing from the blood into the alveolar spaces. Henderson and his associates have shown that when one gas displaces another from a cylindrical tube the interface between the two is not a plane surface. On the contrary, the displacing gas advances in the form of a cone or spike leaving a layer of the gas which is being displaced clinging to the tube's walls. This fact may be demonstrated by displacing air from a glass tube by a puff of smoke (fig. 142). When the current of smoke ceases mixing occurs.

Obtaining a sample of alveolar air

It is clear from the foregoing illustration that in order to obtain a sample of pure smoke as it issues from the end of the tubing all the air must be first swept out. Similarly in order to obtain pure alveolar air a forced expiration must be made and a sample collected as close as possible to the subject's mouth. This is accomplished through the use of the Haldane tube, which consists of a length of hose-pipe 1 inch in diameter and 3 feet long and provided with a mouth piece and sampling bulb as shown in figure 143. The subject after a

FIG. 143. Haldane tube and sampling bulb.

normal expiration makes a forced breath down the tube. Toward the end of this act the sampling bulb, which has been previously evacuated, is squeezed for a moment in order to permit the expired air to be drawn in, and then closed. An all glass syringe may be used instead of the sampling tube. The exact technique used in research is somewhat more complicated than that described above.

The following are the average compositions of inspired, expired and alveolar airs reduced to standard temperature and pressure (S.T.P.).

	Volumes per cent		
	Inspired (atmospheric) air	Expired air	Alveolar air
Oxygen.....	20.94	16.3	14.2
Carbon dioxide.....	0.04	4.0	5.5
Nitrogen (including argon and other inert gases).....	79.02	79.7	80.3

The atmospheric air contains an average of less than 1 per cent water vapor. The lung air contains about 6.2 per cent.

THE DEAD SPACE AIR

The respiratory passages extending from the nostrils to and including the terminal bronchioles (p. 295) constitute what is known as the *anatomical dead space*. The walls of these passages are relatively thick and no gaseous interchange between blood and air can occur across them. The capacity of the anatomical dead space, which was first estimated by Loewy from a cast of the respiratory passages of a dead subject, is about 150 cc. and though variable between individuals is relatively constant for the same person. During an ordinary *inspiration* about 500 cc. of air (tidal air) are inhaled. A proportion of this fresh air (150 cc.) is used to fill the dead space, the air previously in the dead space being, as mentioned above, drawn into the alveoli together with the remainder (350 cc.) of the inspired air. This 350 cc. mixes with a large volume of air (residual and supplemental airs amounting to about 2000 cc.) which remains in the lungs after the previous expiration. During *expiration* alveolar air high in carbon dioxide and low in oxygen is forced from the air sacs. Part of this is exhaled to the outside and part remains within the dead space from which it has displaced the fresh air of the previous inspiration. The expired air is therefore a mixture of alveolar and inspired airs.

The physiological dead space and its estimation

The anatomical dead space as described in the preceding section varies relatively little in capacity, though a moderate increase or decrease may occur as a result of bronchiolar dilatation or constriction. The *physiological*, *virtual* or *effective dead space* are terms applied to the total space within the lung which just prior to expiration contains perfectly fresh air, that is, air which has not diluted the alveolar air or come into contact with the respiratory epithelium. The volume of the physiological dead space varies with the depth of respiration. In shallow breathing fresh air may not be drawn as far as the terminal bronchioles. The physiological dead space would then be less than the anatomical. In ordinary breathing the physiological dead space is considerably larger than the anatomical (i.e., fresh air penetrates beyond the terminal bronchioles), and in deep breathing is enormously increased as a result of the passive dilatation of the respiratory bronchioles and alveolar ducts which after a deep inspiration receive fresh atmospheric air. The advancing margin of the latter, however, as a result of its

spike form, which has been referred to above, is prevented from coming into direct contact with the respiratory epithelium by a layer of vitiated (alveolar) air. Its gases, therefore, like those of the air of the anatomical dead space can reach the respiratory epithelium only by diffusion which, as compared with mechanical mixing, is a slow process.

The volume of the effective dead space, obviously, can only be determined by calculation. It will be equal to the volume of expired air less that of the alveolar air in the expiration. The volume of the alveolar air is derived from the volume of the expired air and the ratio of the percentages of CO_2 in alveolar and expired airs. For example, let us say that (a) the volume of air expired in a single breath is 485 cc. and (b) expired air contains 4 per cent carbon dioxide and (c) alveolar air contains 6 per cent carbon dioxide.

Then the volume of the alveolar air in the expiration is $\left(485 \times \frac{4}{6} =\right)$ 323 cc. The volume of the dead space therefore must be $(485 - 323 =)$ 162 cc. During deep breathing the ratio of the percentage of carbon dioxide in the alveolar air to that in the mixed expired air is about the same as during quiet breathing. Since the volume of the expired air is increased, the effective dead space as calculated by the above method would therefore be increased also.

Example:

Volume of expired air in a single breath	2000 cc.
Carbon dioxide in expired air	4.70 per cent
Carbon dioxide in alveolar air	6.20 per cent
Volume of alveolar air is therefore	$2000 \times \frac{4.70}{6.20} =$
1516 cc. and volume of effective dead space =	$2000 - 1516 =$
	484 cc.

CHAPTER XXXI

THE PHYSICAL PRINCIPLES GOVERNING THE RESPIRATORY EXCHANGES

The interchange of gases which occurs between the atmosphere and the air in the lungs and between the latter and the pulmonary capillaries is termed *external respiration*. Carbon dioxide diffuses from the blood to the air in the air sacs which in turn is freshened by inspired air (p. 310). Oxygen diffuses from the inspired air to the alveolar air and from this into the blood. The gaseous exchange between the systemic blood and the tissues is reversed—oxygen passing from the blood to the tissues and carbon dioxide from the tissues to the blood. This is called *internal respiration*. The gaseous exchanges are governed by physical laws—upon differences in pressures (tension) between the blood plasma on the one hand and the air or tissue fluids on the other.

Hemoglobin serves for the storage and transport of oxygen, sodium bicarbonate serves corresponding purposes for carbon dioxide (see p. 337). The actual interchange of these gases depends, however, upon their relative tensions in the different media, i.e., in the lung air, and in simple solution in the plasma and tissue fluids.

THE KINETIC THEORY OF GASES—DIFFUSION, PARTIAL PRESSURES, ABSORPTION COEFFICIENTS

Any quantity of a gas when placed in a container of whatever size expands its volume until limited by the boundaries of the confining vessel. This fact is explained upon the theory that the gas molecules are in continuous motion, moving through space at high velocity and being deflected from their course only upon coming into collision with other gas molecules or with the boundaries of the space itself from which they rebound and collide ceaselessly. Such collisions constitute a bombardment upon the confining walls which is responsible for what is called the pressure or tension of the gas. The greater the number of molecules in any given space the greater, obviously, will be the number bombarding the vessel's walls in a given time. So, if the capacity of the space is reduced the molecules are brought closer together. The rate of bombardment upon a unit of surface will increase and the pressure of the gas will rise (see *Boyle's Law* below). A rise in temperature increases the velocity of the molecular

movements, increases the rate of bombardment and the force of the impacts. The pressure in consequence increases (*Charles' Law*).

In all circumstances, the gas molecules as a result of their movements will in time distribute themselves evenly throughout the space in which they are confined and consequently the pressure will be the same upon all parts of the limiting surface. In other words, although at the start the molecules may be in greater numbers (concentration) in one part of the space than in another, even distribution is soon brought about and the pressure throughout all parts of the space becomes equal. This behavior of a gas whereby the equalization of its molecular concentration occurs is spoken of as *diffusion*. If we should deal with a mixture of two or more different gases instead of with a single gas it would be found that each component in the mixture behaved as though present alone. Its molecules would become distributed evenly throughout the mixture and its pressure would depend upon its concentration without regard to the concentrations of the other component gases (*Law of partial pressures*).

If two samples of a gas, of different concentrations be placed one on each side of a membrane permeable to that gas, diffusion also occurs until the tensions on the two sides of the membrane are equal; as in the case of a gas mixture each gas behaves as though present alone.

When a gas or a mixture of gases lies in contact with the surface of a liquid, the molecules of each gas penetrate the liquid and become dissolved in it until the tensions of that particular gas within and without the liquid are equal. The gas is then said to be equilibrated with the liquid (*Law of solubility of gases*). On the other hand, if the liquid be now exposed to a lower pressure of the gas the molecules which had undergone solution at the higher pressure escape until equilibrium is restored at the lower level. Soda water, for example, is water which has been equilibrated with carbon dioxide at a high pressure. When the cork is removed from the bottle containing the surcharged liquid, effervescence occurs. Molecules of carbon dioxide are given off until the pressure of the dissolved gas equals that of the carbon

dioxide (0.3 mm. Hg) in the atmosphere. A gas at different tensions in two liquids also comes into equilibrium whether the liquids are in direct contact or are separated by a membrane permeable to the gas. Also the actual *amount* of gas which will undergo solution at a given pressure varies with the particular gas and with the liquid. If distilled water for example be exposed to oxygen at a pressure of 760 mm. and a temperature of 0°C. each 100 cc. will take up 4.9 cc. of the gas. Oil, on the other hand, under the same conditions or pressure and temperature will absorb a great deal more. Therefore if samples of water and oil are exposed to the atmosphere though the gas pressures in the three media are identical, the volumes of the atmospheric gases in 100 cc. (volumes per cent) of each medium will be widely different.

The quantity of a gas (measured at standard temperature and pressure) which can be absorbed by 1 cc. of a liquid at 760 mm. Hg is called the

TABLE 23

Absorption coefficients of various gases in distilled water at different temperatures

TEMPER- ATURE	OXYGEN	CARBON DIOXIDE	CARBON MONOXIDE	NITROGEN
0	0.049	1.71	0.035	0.024
20	0.031	0.87	0.023	0.016
40	0.023	0.53	0.018	0.012

absorption coefficient of the gas for that particular liquid. Thus the absorption coefficient of oxygen in water at 0°C. is 0.049 and of carbon dioxide 1.71; the coefficient varies inversely with the temperature (see table 23). The presence of dissolved solid substances in the water will reduce the absorption coefficient of these gases. The values for the body fluids are therefore slightly less than those given above. Thus the coefficient of absorption of oxygen in plasma at body temperature (37°C.) is 0.024 and of carbon dioxide 0.510.

The rate of diffusion of a gas through a liquid is in direct proportion to the absorption coefficient of the gas in that liquid and inversely proportional to the square root of its molecular weight. The diffusion rate of carbon dioxide through a wet membrane is about 30 times greater than that of oxygen when the two gases are under identical conditions. For general physiological work the *diffusion coefficient* of oxygen has been defined by Krogh as the number of cubic centimeters of the gas which will diffuse 0.001 mm. distance over a square centimeter of surface, per minute, at a pressure of 1

atmosphere. It varies for different tissues and body fluids and increases 1 per cent per degree Centigrade.

The diffusion coefficients for oxygen through the following materials at body temperature were found:

Water.....	0.51
Gelatin 15 per cent.....	0.45
Muscle.....	0.31
Connective tissue.....	0.18

The diffusion coefficient of oxygen through the pulmonary epithelium of the intact animal is defined as the number of cubic centimeters which are absorbed per minute per millimeter of mean pressure difference between the blood and alveolar air. The coefficient varies in different individuals from 23 to 45 during rest and from 37 to 56 during exercise. If, for example, the mean difference between the oxygen tensions of the blood and alveolar air should be 10 mm. Hg and the coefficient 25 mm., then (10 × 25 =) 250 cc. of oxygen will be absorbed per minute. The increase in the coefficient during exercise is ascribed to the opening up of more capillaries. The differences observed between individuals are probably dependent upon the sizes of the alveoli, the thickness of the alveolar epithelium and the mean capacity of the lungs. The diffusion coefficient of carbon dioxide through the alveolar epithelium is around 500 during rest and 800 during exercise.

SUMMARY OF THE GAS LAWS

(1) *Boyle's Law.* When the volume of a gas is altered, the temperature remaining constant, the pressure varies inversely, i.e., the product of the pressure and the volume remains constant. If the space wherein a certain gas is confined be reduced by half the gas pressure is doubled and vice versa.

(2) *Law of Charles (or Gay-Lussac).* For each rise in temperature of 1°C. a gas kept at constant pressure expands by $\frac{1}{273}$ of its volume at 0°C. The volume of a gas at constant pressure is therefore proportional to its absolute temperature (–273°C.).

(3) *The Law of Partial Pressure (Dalton's Law).* The pressure exerted by a gas in a mixture of gases is equal to the pressure which the same quantity of that gas would exert were no other gases present. It follows that the total pressure of a mixture of gases is equal to the sum of the pressures of its component gases. For example, the atmosphere (dry) exerts a pressure of 760 mm. Hg. The gases of which it is composed—oxygen, nitrogen and carbon dioxide are present in the proportions of 20.96 per cent, 79 per cent and 0.04 per cent respectively. The partial pressure exerted by oxygen is therefore $\frac{20.96}{100} \times 760 = 159.2$ mm. Hg and of carbon dioxide $\frac{0.04}{100} \times 760 = 0.3$ mm. Hg.

Air in contact with water is continually receiving water molecules from the surface of the liquid. This water vapor follows Dalton's Law exerting a pressure independently of the other gases, and proportional to the quantity present in the air. The higher the temperature the greater is the quantity of water which the air will hold before becoming saturated and the greater consequently will be the tension of aqueous vapor.

The air in the lungs has a temperature of about 37°C. and is usually stated to be fully saturated with water vapor; the latter, therefore, exerts a pressure of 47 mm. Hg.¹ The air after leaving the lungs falls in temperature, some of the water vapor condenses and the latter in consequence is much less. The tension of water vapor in room air (18°C.) would be no more than 15.5 mm. Hg, even though the air were fully saturated, and is usually around 4 or 5 mm. Hg. The aqueous tensions of air (saturated) at various temperatures are given in table 24.

TABLE 24
Tension of aqueous vapor and water in grams in moisture-saturated air at different temperatures

TEMPERATURE	TENSION OF AQUEOUS VAPOR	WATER PER CUBIC METER OF AIR
°C.	mm. Hg	grams
0	4.6	4.9
5	6.5	6.8
10	9.1	9.4
15	12.7	12.8
20	17.4	17.2
30	31.6	30.1
37	47.1	

In the measurement of the respiratory gases the volumes are expressed dry (i.e., less the aqueous vapor, though actually no correction for this is required) and at standard temperature and pressure (S.T.P.)—760 mm. Hg and 0°C. The individual gases, carbon dioxide or oxygen, are then expressed as percentages of this dry volume.

In order to arrive at the tension of one or other gas from its percentage in dry air, the figure for the barometric pressure less the aqueous tension must of course be used as the basis for calculation. For example, if the carbon dioxide percentage in a sample of alveolar air (dry) is 5.6 per cent and the barometric pressure, and so of course the total gas pressure of the alveolar air,

¹ Christie and Loomis from direct measurements have obtained a lower value for the aqueous tension of alveolar air than the usually accepted one of 47 mm. Hg, (namely 45 mm. Hg). They claim that the alveolar air is not fully saturated and that the temperature of the lung is lower than has been assumed. Hyperpnea they found reduced the aqueous tension by as much as 7 mm. Hg. Holding the breath increased it by 0.5 mm. Hg.

is 760 mm. Hg, then the tension of carbon dioxide in the alveolar air must be

$$\frac{5.6}{100} \times (760 - 47) = 39.9 \text{ mm. Hg}$$

Similarly when the O₂ percentage in dry alveolar air is 14.2 the oxygen tension is

$$\frac{14.2}{100} \times (760 - 47) = 101.2 \text{ mm. Hg.}$$

(4) *Henry's Law of the Solution of Gases.* If the temperature remains constant then the quantity of a gas which goes into solution in any given liquid is proportional to the partial pressure of the gas.

THE EXCHANGE OF GASES IN THE LUNGS
THE PARTIAL PRESSURES OF THE GASES IN THE LUNG AIR

In table 25 are given average figures for the partial pressures of oxygen, carbon dioxide and nitrogen in inspired, expired and alveolar airs.

TABLE 25			
BAROMETER 760 MM. Hg	PARTIAL PRESSURE		
GAS	Inspired air	Expired air	Alveolar air
	mm. Hg	mm. Hg	mm. Hg
Oxygen.....	158.25	116.2	101.2
Carbon dioxide.....	0.30	28.5	40.0
Nitrogen.....	596.45	568.3	571.8
Aqueous vapor.....	5.00	47.0	47.0
Totals.....	760.00	760.0	760.0

The fall in oxygen pressure from inspired to alveolar air and in the reverse direction for carbon dioxide will quite evidently promote the free interchange of these gases within the lung. The interchange of gases between inspired and alveolar airs is reflected in the intermediate values shown for the gas pressures in the expired air.

The alveolar oxygen and carbon dioxide tensions vary with the minute volume (p. 350). During hyperpnea the CO₂ tension falls and the O₂ tension rises. When the breath is held or during periods of apnea changes of a reverse order occur.

Nitrogen, so far as respiration is concerned is inert. A small but constant amount (about 0.83 volume per cent) of the gas is taken up and dissolved in the plasma but it is neither used nor

produced within the body, the quantities in arterial and in venous blood being identical. It will be noted, however, that the percentage of this gas is higher in expired than in inspired air (see p. 311). This is due not to any absolute increase in the quantity of nitrogen but is related to the reduction of the total volume of the respiratory gases resulting from the greater quantity of oxygen absorbed than carbon dioxide put out.

THE PARTIAL PRESSURES OF OXYGEN AND CARBON DIOXIDE IN BLOOD

In table 26 are given the tensions of oxygen and carbon dioxide in arterial and in venous blood. The venous blood, it will be seen, has a lower tension of oxygen (by 60 mm.) than the alveolar air but a higher tension of carbon dioxide (by 6 mm.). It is to be remembered that the pulmonary capillaries and the air in the alveoli are

TABLE 26
Gas tensions in arterial and in venous blood

separated by delicate membranes freely permeable to these gases. The pressure gradients are favorable to a rapid inward diffusion of oxygen (from alveolar air to blood) and an outward diffusion of carbon dioxide (from blood to alveolar air). Equilibrium is quickly established between the respiratory gases in the alveolar air and in the blood of the pulmonary capillaries. Since the diffusion coefficient of carbon dioxide through the pulmonary membrane is much higher than that of oxygen, the pressure gradient need not be so high for the former gas. It will be seen from tables 25 and 26 that the tension of carbon dioxide in the blood leaving the lungs, i.e., in the mixed arterial blood, is the same as that in the alveolar air. Indeed, it is the usual practice, when one wishes to know the arterial CO₂ tension, to determine that of the alveolar air and assume that the two are identical. It has been shown, however, by Bock and associates that a slight difference

(0.5 mm. Hg) does exist. The tension of oxygen in arterial blood is from 5 to 10 mm. Hg below that of the alveolar air, i.e., from 95 to 100 mm. Hg.² (See fig. 144 and footnote on p. 317.)

Gaseous equilibrium is attained not instantaneously but progressively along the course of the pulmonary capillary. Diffusion is rapid at the venous end but as blood and alveolar air approach equilibrium the diffusion process necessarily becomes slower. The length of the capillary and the rate of the blood flow through it are factors which must determine the extent to which equilibrium occurs. As a matter of fact though the circulation through the lungs be speeded up several fold the oxygenation of the blood or the elimination of carbon dioxide is little impaired. It is also true that though the blood coming to the lungs has given up 50 per cent or more of its oxygen-

FIG. 144. Curves showing relationship between O₂ and CO₂ tensions in alveolar air (dotted lines) and arterial blood (continuous lines) of rabbit. Gas tensions, in per cent of an atmosphere, along ordinate; time along abscissa. (From A. and M. Krogh.)

load to the tissues, the uptake of oxygen and the elimination of carbon dioxide are effected without difficulty by healthy lungs, for the diffusion rates are greatly increased as a result of the larger differences which must then exist between the gas tensions in alveolar air and venous blood.

The tensions of oxygen and carbon dioxide in human arterial blood may be determined by bringing a small bubble of air into contact with a sample of the blood obtained by arterial puncture. The method employed for the purpose is an adaptation to man (Barcroft and Nagahashi) of a method originally invented by Krogh for animals (see fig. 145). After the gases in the air have come into equilibrium with those dissolved in the blood the small bubble is analyzed and its composition determined. The gas tensions are

² Bock and his associates find a much greater difference than this between the oxygen tension of the alveolar air and arterial blood

then calculated from their percentages (p. 315). Since no gaseous exchanges occur across the walls of the arteries, the tensions so determined are those of the mixed arterial blood of the pulmonary capillaries. It has already been mentioned that the arterial carbon dioxide tension is usually obtained from an analysis of alveolar air. The gas tensions of the blood coming to the lungs—the *mixed venous blood*—is usually determined in man by indirect methods (p. 228). In animals mixed venous blood may be obtained from the right ventricle by puncturing the chest wall with a hollow needle attached to a syringe.

THE VOLUMES OF OXYGEN AND CARBON DIOXIDE IN BLOOD

Knowing the respective absorption coefficients for oxygen and carbon dioxide in plasma, and the gas pressures, the volume of each gas in simple solution in 100 cc. of plasma can be readily calculated (table 27). For example, the absorption coefficient of oxygen in plasma is 0.023 at body temperature and at a pressure of 760 mm. Hg. At the partial pressure of oxygen in arterial blood the plasma should hold in solution $\frac{100}{760} \times 0.023 = 0.003$ cc. of oxygen per cubic centimeter or 0.3 volume per cent. In *whole blood* the quantity of oxygen in *simple solutions* is less—only 0.24 volume per cent. The absorption coefficient of carbon dioxide in plasma (0.51) or of whole blood is higher (0.48) than that of oxygen but the partial pressure of carbon dioxide to which arterial blood is exposed in the lung is lower (40 mm. Hg) than that of oxygen. The quantity of the former gas in simple solution in whole blood is therefore $\frac{40}{760} \times 0.48 = 2.5$ volumes per cent.

Nineteen volumes per cent of oxygen and from 40 to 55 volumes per cent of carbon dioxide can be removed from arterial blood. The proportions of these gases present in simple solution must, therefore, be only a small fraction of the quantities held in the blood in other ways. They are present in chemical combination—oxygen with hemoglobin and carbon dioxide mainly as bicarbonate (see Chap. XXXIII).

Blood normally contains about 15 grams of hemoglobin per 100 cc. Since 1 gram of hemoglobin carries a maximum of 1.34 cc. of oxygen, arterial blood would, therefore, when saturated to its full capacity, contain about 20 cc. of oxygen. Blood as it leaves the lungs is from 94 to 96 per cent saturated with oxygen so that the hemo-

FIG. 145. Krogh's microtonometer. A is an enlarged view of an equilibration chamber constituting the lower part of B(1) but which is shown only in part in the latter drawing. A is filled with saline solution through the side tube. 1, a narrow tube into which the specimen of blood is introduced; 2, an air bubble. The lower end of 1 is connected by rubber tubing to a cannula inserted into a blood vessel; the blood issues from a narrow opening at the upper end of the tube 1 in a fine jet and plays upon the bubble. After the gases in blood and bubble have come into equilibrium the latter is drawn into the graduated capillary tube shown in B, by means of the screw-plunger (4), and analyzed according to the following procedure. The volume of the bubble is first measured, it is next drawn into a solution of KOH which absorbs the CO_2 , then returned to the graduated tube and measured again; the difference between the two measurements gives the amount of CO_2 which it contained. The bubble is then passed through a solution of potassium pyrogallate, to absorb the O_2 , and its volume measured a third time. C is a model with an attached cannula which can be inserted directly into a blood vessel.

globin holds at this degree of saturation only about 19 cc. of oxygen per 100 cc. of blood.*

* Since the blood in passing through the capillaries of an air sac comes into equilibrium with the air of that air sac as described on page 310 the statement that the arterial blood has a tension less than that of the alveolar air and is only from 94 to 96 per cent saturated, requires explanation. The discrepancy is explained as follows. The air sacs are not all ventilated to the same extent; in some the O_2 tension is higher, in some lower than that of the alveolar air as determined upon a sample. In other words the O_2 tension of a sample of alveolar air is an average of the O_2 tensions of the air in all the air sacs. But, when we come to consider the blood coming, not from a single air sac, but from the lung as a whole—i.e., the *mixed arterial blood*—

The quantity of oxygen or of carbon dioxide contained in a given sample of blood (*oxygen or*

carbon dioxide content) is determined by transferring the sample to a blood-gas apparatus (Haldane

it becomes evident that while an under-ventilated air sac will lower the oxygen tension and so the oxygen saturation of the hemoglobin, an over-ventilated one cannot compensate this effect to any significant extent. The O₂ in solution (upon which the O₂ tension directly depends) is in equilibrium with that combined in hemoglobin and it is evident from the shape of the O₂ dissociation curve of hemoglobin that a rise in oxygen tension above 100 mm. Hg will saturate the blood very little more whereas a fall of 20 mm. Hg or so will reduce the saturation very materially (see also shallow breathing p. 365).
The variation between individuals in the O₂ saturation of the arterial blood is attributed to the different degrees to which uneven ventilation of the air sacs occurs and also to slight differences in the shapes of the dissociation curves. It was first shown by Barcroft that the O₂ dissociation curve is not precisely the same for all persons. The dissimilarities are due apparently to slight differences in the chemical constitution of the globin part of the hemoglobin molecule.

or Van Slyke) and then freeing all the oxygen from the hemoglobin by the addition of potassium ferricyanide, or all carbon dioxide from combination by the addition of acid. Precaution must be taken not to permit the sample to come in contact with air. Since the cell wall is not freely permeable to K₃Fe(CN)₆ the corpuscles should be first laked by ammonia or saponin solution. Haldane showed that all the oxygen in blood is liberated by this procedure and the oxyhemoglobin is turned into methemoglobin (p. 00). The method most commonly used is that of Van Slyke (described in Peters and Van Slyke, Quantitative Clinical Chemistry (Methods)). The *oxygen capacity* of a sample of blood is calculated by exposing it to air or oxygen and determining the amount which it then contains, that is, when the hemoglobin is completely saturated. The ratio of oxygen content to oxygen capacity × 100 gives the percentage saturation of the blood with oxygen. Since the quantity of oxygen (1.34 cc.) which will combine with 1 gram of hemoglobin is known, the hemoglobin content of a specimen of blood may be calculated from the quantity of O₂ in the blood when fully saturated, i.e., from its oxygen capacity. For example, if a sample of blood has an oxygen capacity of 10 volumes per cent its hemoglobin content is $\left(\frac{10}{1.34} = \right)$ 7.5 grams per cent or 50 per cent of the normal.

CHAPTER XXXII

THE TRANSPORT AND DELIVERY OF OXYGEN TO THE TISSUES

Hemoglobin serves for the storage and transport of oxygen. The small amount of oxygen in simple solution (about 1 per cent of the total) is negligible when one considers the oxygen requirements of the tissues (250 cc. per minute) even under ordinary conditions. If the blood could hold no more than this it would be necessary for some 120 liters to circulate through the tissues each minute, even assuming that all the oxygen were given up during each circulation. Nevertheless, the gas in simple solution is of the utmost importance since it is in equilibrium with the alveolar air on the one hand and on the other determines the quantity of oxygen which shall be held in combination with the hemoglobin. This will be made clear from a study of the oxygen dissociation curve for hemoglobin.

FIG. 146. Series of tonometers. The numbers denote the pressure of oxygen in mm. (After Barcroft.)

THE DISSOCIATION CURVE OF HEMOGLOBIN

Oxygen enters into chemical combination with the iron of the hemoglobin molecule (see p. 43) to form oxyhemoglobin. Each atom of the metal unites with two atoms of oxygen. The remarkable feature of the union of oxygen with hemoglobin is the readiness with which the gas is released from combination when its tension in the surrounding medium is reduced. Hemoglobin from which the oxygen has dissociated is called reduced hemoglobin. The relationship between the partial pressure of oxygen and the percentage saturation of the hemoglobin with the gas—i.e., the proportion of oxyhemoglobin to reduced hemoglobin—can be shown in the form of a curve—the *oxygen dissociation curve of hemoglobin*. The curve for a

solution of hemoglobin in distilled water is obtained in the following manner. Several samples of the hemoglobin solution are placed each in a separate closed vessel known as a tonometer (fig. 146). The respective samples are then exposed to known oxygen tensions: 0, 10, 20, 40 and 100 mm. Hg. The tonometers are rotated continuously in a water bath at body temperature. The solution is thus spread out as a thin film over the interior surface of the vessel. After equilibrium has been attained the proportion of oxy- to reduced hemoglobin is determined. When 100 per cent saturated the solution contains about 20 volumes per cent of oxygen. When a quarter or half saturated

FIG. 147. Oxygen dissociation curve of a solution of hemoglobin. (After Barcroft.)

it therefore contains 5 to 10 volumes respectively. The results are plotted on a chart with the oxygen tensions along the abscissae and the percentage saturation along the ordinates as shown in figure 147. The curve is a rectangular hyperbola. Huffer obtained such a curve for hemoglobin from calculations based upon the law of mass action (see below).

If the foregoing procedures are carried out with blood instead of with a hemoglobin solution a different type of curve is obtained as shown in figure 148. It is doubly inflected or S-shaped.

The dependence of the oxygen saturation of

hemoglobin in an aqueous solution upon the partial pressure of the gas is in accordance with the law of mass action which states that "the velocity of chemical change is proportional to the product of the concentrations of the reacting substances." In this case the reacting substances are reduced hemoglobin and oxygen. The reaction is reversible and is represented thus

It is evident that in the foregoing procedures the tension of oxygen in the hemoglobin solution, or in the plasma in the case of whole blood, came into

FIG. 148. Composite curve to show the degree of variation in the oxygen dissociation curve of human blood as determined upon a number of persons. In each case the blood was exposed to an atmosphere containing the same percentage of CO_2 as that of the alveolar air of the individual examined. Ordinates, percentage saturation; abscissae, oxygen pressure. (After Barcroft.)

equilibrium with the oxygen pressure of the atmosphere introduced into the tonometer. Then, the concentration of the dissolved oxygen must be proportional to the partial pressure of the gas to which the solution was exposed (p. 313). So, if C_o = concentration of O_2 , C_r = concentration of reduced hemoglobin and C_a = concentration of oxyhemoglobin, then the velocity of the reaction of Hb with O_2 to form HbO_2 will be proportional to the product of C_o and C_r multiplied by a constant k , and the reverse reaction, the dissociation of oxyhemoglobin (HbO_2) to reduced hemoglobin (Hb) and oxygen, will be proportional to C_a multiplied by another constant k_1 . Thus:

$$k(C_o \times C_r) = k_1(C_a)$$

At any given tension of oxygen in the opposite reactions, the formation of oxyhemoglobin and its dissociation proceed simultaneously until equilibrium becomes established. A simple reaction of this nature will explain the dissociation curve of a hemoglobin solution but the S-shaped curve of blood is thought to be due to a series of reactions. It will be recalled that natural hemoglobin (p. 43) has a molecular weight (68,000), four times greater than was previously supposed. It may therefore be given the symbol Hb_4 . It is thought that each molecule of hemoglobin combines with four molecules of oxygen, $\text{Hb}_4 + 4\text{O}_2 \rightarrow \text{Hb}_4\text{O}_8$. The oxygen dissociation curve calculated by the application of the law of mass action to this equation has more pronounced S-shape than any actually observed for blood. On the other hand, the curve calculated from the equation $\text{Hb}_4 + \text{O}_2$ is hyperbolic (fig. 147). It is believed, therefore, that the combination of oxygen with hemoglobin under physiological conditions, four separate but simultaneous reactions take place.

The combination of all these reactions, it has been suggested, is responsible for the special S-shape of the oxygen dissociation curve (figs. 148 and 149).

Certain features of the oxygen dissociation curve of whole blood shown in figure 149 are of the most physiological importance. It will be seen that at 100 mm. Hg, i.e., at the partial pressure of oxygen in arterial blood, hemoglobin is about 95 per cent saturated. Increasing the oxygen tension beyond 100 mm. Hg will therefore increase very little the quantity of oxygen with which the hemoglobin can combine. The flattening out of the upper part of the curve means that relatively little reduction in the percentage saturation of the hemoglobin occurs until the oxygen pressure falls to about half its normal value. At an oxygen tension of 70 mm. Hg the hemoglobin is about 90 per cent saturated. The slope of the lower part of the curve is such that a given fall in oxygen pressure causes a much greater desaturation of the hemoglobin. The behavior of hemoglobin as indicated by the shape of its curve therefore favors a nearly maximum uptake of oxygen in the lungs so long as the oxygen pressure is above 70 mm. Hg and a rapid liberation of the gas at lower oxygen pressures which prevail in the tissues. It will be realized from a glance at the hyper-

ve shown in figure 147 how unsuitable hemoglobin would be as a carrier of oxygen if it behaved in the manner indicated by this curve. The hemoglobin would show a great avidity for oxygen in the lungs but would not yield up its oxygen until the partial pressure in the tissues had fallen to a very low level. At the pressures which exist in the tissues the rate of dissociation of hemoglobin would be many times slower than the rate of its formation. Hemoglobin would thus be worthless as an oxygen carrier. As it is, the oxygenation of hemoglobin in the lungs and the reduction in the tissues proceed at practically equal rates.

FIG. 149. Dissociation curves of human blood, exposed to 0, 3, 20, 40 and 90 mm. CO_2 . Ordinates, percentage saturation. Abscissae, oxygen pressure. (after Barcroft.)

THE EFFECTS OF REACTION AND OF TEMPERATURE UPON THE SHAPE OF THE OXYGEN DISSOCIATION CURVE

The effect of dissolved inorganic salts upon the shape of the dissociation curve appears to be of less importance than was previously supposed. Hemoglobin solutions free from salts give the S-shaped curve when special precautions are taken to prevent a change (denaturation) occurring in the natural constitution of the hemoglobin complex. Denaturation may result from bacterial action, "ageing" or other agencies.

The oxygen dissociation curve of hemoglobin is so sensitive to acid that it has been used by Barcroft and associates as a basis of a method for measuring changes in blood reaction. A shift of the curve to the right, i.e., when the blood absorbs less oxygen at a given pressure, would indicate an increase in H^+ ion concentration, and a shift to the left the reverse change.

A change in the reaction of the blood toward the acid side causes the curve to flatten toward the right, i.e., the affinity of hemoglobin for oxygen is reduced. Carbon dioxide and lactic acid liberated during tissue activity will exert this effect. The influence exerted by CO_2 was discovered by Bohr and is usually referred to as the Bohr effect¹ (see figure 149). Temperature exerts a similar effect upon the dissociation curve. These agencies, therefore, cause the hemoglobin to liberate its oxygen more readily at the lower oxygen tensions but exert little effect upon the uptake of oxygen at the higher tensions; they cause the reactions involved in the breakdown of oxyhemoglobin to be speeded up, the equilibria shown on page 320 being shifted to the left. Alkalis and a fall in temperature will of course have the reverse effect.

THE UNLOADING OF OXYGEN IN THE TISSUES

It is now possible to give a connected account of the manner in which oxygen is taken up from the lungs by the blood and supplied to the tissues. The absorption of oxygen from the alveolar air is the result simply of diffusion (pp. 313 and 314). The oxygen tension in the arterial blood is lower (never higher) than that of the alveolar air. This is so, even at high altitudes where the alveolar oxygen tension is greatly reduced (p. 361). There is no reason, therefore, to believe that the pulmonary epithelium actually secretes oxygen into the blood.² The percentage saturation of the hemoglobin is dependent upon the oxygen tension of the blood, i.e., the amount of the gas in simple solution, which, as just mentioned, is governed in turn by the oxygen pressure in the alveolar air. The hemoglobin in the blood leaving the lungs is about 95 per cent in the form of oxyhemoglobin (i.e., it is 95 per cent saturated).

Practically no oxygen is lost from the arterial blood until the capillaries have been reached, so the blood reaches the periphery with a high pressure head of oxygen. The oxygen tension of the tissue fluids and cells is relatively low; a flow of oxygen from the plasma across the capillary membrane results. This, of course, will tend to lower the oxygen tension of the capillary blood plasma and upset the equilibrium between it and the oxyhemoglobin. Dissociation of the latter occurs to sustain the partial pressure of the plasma oxy-

¹ The view that the pulmonary epithelium does not always play the rôle of a passive membrane but is capable of actively secreting oxygen into the arterial blood was advanced by Bohr and has been elaborated by Haldane.

gen. In other words a steady flow of oxygen from red cell to tissue cell is maintained as a result of the slope in partial pressure of the gas. The rise in temperature and liberation of carbon dioxide and lactic acid in the tissues, as we have seen, shifts the oxygen dissociation curve to the right and so accelerates the decomposition of the oxyhemoglobin.

COEFFICIENT OF OXYGEN UTILIZATION

In passing through the capillaries the blood under ordinary circumstances loses from a fifth to a quarter of its oxygen store. That is, the hemoglobin in the blood coming to the lungs has an oxygen saturation of from 70 to 75 per cent, the tension of the gas being between 35 and 40 mm. Hg. The figure used to express the proportion of the total oxygen content of the blood which is given up to the tissue is called the *coefficient of oxygen utilization*. Thus, if the oxygen content of the arterial blood is 19 volumes per cent and that of the venous blood 12 volumes per cent (i.e., arterio-venous oxygen difference 7 per cent) the coefficient is ($\frac{7}{19} =$) 0.36. The coefficient varies considerably for different tissues and for the same tissue in accordance with the degree of its activity and rate of blood flow. During very strenuous exercise for example the hemoglobin of the venous blood coming from the muscles may be only 25 per cent saturated with oxygen. Heart muscle has a very high coefficient.

THE RESPIRATORY QUOTIENT

The ratio of the volume of carbon dioxide produced by a tissue to the volume of oxygen absorbed

$$\frac{\text{Volumes CO}_2 \text{ produced}}{\text{Volumes O}_2 \text{ absorbed}}$$

is called the respiratory quotient of that particular tissue. The ratio of these volumes as determined from the expired air will be the respiratory quotient of the body as a whole (p. 523).

THE MANNER IN WHICH THE CALL OF THE TISSUES FOR OXYGEN IS MET

Increased activity of any tissue always entails an increased oxygen consumption which may be several times the resting value. Increase in the oxygen supply to the tissue above its requirement on the other hand does not increase the oxygen usage. The tissue takes what oxygen its activity at the moment demands but no more.

There are two ways in which a greater demand of the tissues for oxygen may be met. By (1) increasing the total blood flow through the tissue and maintaining a high intracapillary oxygen pressure, and (2) raising the coefficient of oxygen utilization, i.e., increasing the quantity of oxygen abstracted from a given volume of blood.

Both these factors come into play but the extent to which each operates is not the same for different tissues. The coefficient of oxygen utilization is increased by establishing a steep oxygen pressure gradient between the plasma within the capillaries and the tissue cells. That is, the quantity of oxygen used (Q) will, other things being equal, be proportional to the difference in intracapillary and intracellular pressures (P_c and P_t respectively), thus:

$$Q \propto P_c - P_t$$

An increase in the pressure gradient is brought about, (a) by the action of acids (carbonic and lactic) and a rise in temperature both of which accelerate the decomposition of oxyhemoglobin and so maintain a high intracapillary oxygen pressure, (b) by lowering the oxygen tension within the tissue cells, and (c) by shortening the distance through which the oxygen must diffuse, i.e., by opening up more capillaries and so reducing the radius of the cylinder of tissue supplied by each capillary (fig. 150). The oxygen tension of resting skeletal muscle is low—about 20 mm. Hg or less. During activity therefore little increase in the pressure gradient can result from a reduction in the intracellular oxygen tension even if this falls to zero. In muscular activity, the greatly increased oxygen supply is the result mainly of augmented blood flow and the increase in the coefficient of oxygen utilization produced by (a) and (c) above.

During strenuous exercise the coefficient of oxygen utilization of the muscles may be more than doubled and the blood flow through the muscles increased several fold. If, for example, a two-fold increase in the coefficient of oxygen utilization occurred together with a four-fold increase in blood flow the actual amount of oxygen delivered to the contracting muscles would be increased ($2 \times 4 =$) 8 times. In man the oxygen consumption of the muscles may actually be increased by from twenty to thirty times or in an athlete even fifty times. It has been found that the resting gastrocnemius of the cat consumes on the average 0.003 cc. of oxygen per gram of muscle

per minute. During activity the blood flow increases some 6 times, and the oxygen consumption over seven-fold. The increase in oxygen consumption must be brought about in part by the removal of more oxygen from each unit of blood. A marked rise in the coefficient of oxygen utilization has been demonstrated by several observers in man during exercise.

A

B

FIG. 150. The pressure of oxygen in the tissues. The dot in the center of each series of concentric circles represents a capillary containing blood with an oxygen pressure of 30 mm. Hg. Between each circle and the next larger one there is a fall of 5 mm. Hg. in oxygen pressure. At the points marked X (in A) the oxygen pressure is therefore zero, and the tissue is asphyxiated. In B, extra capillaries have opened up and there is a finite oxygen pressure throughout the tissue. (After Barcroft.)

The circulation rate (p. 224) in man may increase nearly ten-fold during muscular exercise. It is certain, however, that there is also a redistribution of the blood, that is, a greater *proportion* of the total blood volume is driven through the muscles than during rest. The actual blood flow through the active muscles may, for this reason, be twenty times or more greater than the flow during rest, though the blood flow through the body as a whole is increased only ten times or so. In exercise, then, though the red cell has a shorter

stay in the capillary it unloads more of its oxygen, as indicated by the increase in the coefficient of oxygen utilization. The actual speed of the red cell through the capillary is not, however, as great as might be thought from the increased volume of blood flowing through the muscles, for the opening up of more capillary channels and the consequent increase in the total cross section of the blood stream (p. 148) tends to prevent any excessive acceleration of the red cell's passage.

INTRACELLULAR OXIDATION AND THE BIOLOGICAL TRANSFORMATION OF ENERGY

By A. M. WYNNE

No problem in the entire field of physiological and biochemical investigation is of greater fundamental significance than is that which concerns the transformation of energy in living organisms; for it is through the transformation of energy that life itself is made possible. What are the special characteristics which distinguish living matter from all other structures? This question cannot be answered in precise terms: the word 'living' is used to embrace such a wide variety of structures that no universally acceptable characterization of living matter is possible. Indeed, the transition from the 'living' to the 'non-living' state is so gradual that it is quite impossible to draw a sharp line of division between the two states. But, if one may exclude the border-line systems and confine the discussion to the great variety of structures concerning whose living nature there can be no disagreement, it is possible to identify certain properties which distinguish the living cell from other structures. For example, the structure of the cell, with its multiplicity of surfaces, makes possible the orderly interplay and progression of a great variety of chemical reactions which take place within the boundaries of the cell and are co-ordinated with reactions in neighboring cells and fluids. Moreover, the living cell is able to liberate from cellular metabolites their stores of potential chemical energy in the form of free energy and to utilize free energy in the performance of work of many kinds, including the synthesis of specific cellular substances of varying complexity from non-specific materials. All this is accomplished at ordinary temperatures and in media which are nearly neutral. It is true, of course, that only a relatively small and somewhat variable fraction, usually not more than 20 or 25 per cent, of the total free energy released in catabolic reactions can be utilized in the anabolic and dynamic activities of the organism. The remainder is transformed into heat; and, since the living organism cannot utilize heat energy in the performance of work, a large proportion of the energy released in cellular metabolism serves no useful purpose except that of maintaining the temperature of the organism, and is soon lost to the environment.

"The living cell is not only the smallest independent unit of biological structure but it is also the smallest unit capable of maintaining complete metabolic activity". The metabolic activity of the cell is an expression of the dynamic inter-relationships of chemical reactions, many of which are concerned with the liberation, interchange or utilization of free energy; the great majority of the reactions are, moreover, controlled and co-ordinated by specific colloidal catalysts, called enzymes, functioning in heterogeneous media in which surfaces and spatial orientation play a predominant role.

It is the main purpose of this section to discuss briefly some of the enzymes which are concerned with the oxidation and reduction of cellular substances, and, in particular, to inquire into their mode of action in relation to the oxidation-reduction systems of the cell which are responsible for the transport of hydrogen and electrons from the metabolites to molecular oxygen. These enzymes are essential components of the catalytic systems which exercise control over the intracellular oxidative reactions which provide the organism with a large proportion of its supply of free energy. Later in the chapter, reference will be made to recent investigations of coupled reactions in which energy released in oxidative processes is trapped in the form of energy-rich phosphate bonds and is subsequently made available to the cell for the performance of work.

Oxidations in general can be accomplished by the addition of oxygen, by the removal of hydrogen or by the withdrawal of electrons. All three methods are fundamentally similar in principle; for, in each case, there is a loss of one or more electrons from the substance undergoing oxidation. Reduction, on the other hand, means, primarily, a gain of electrons, though the actual mechanism of reduction may involve the addition of hydrogen or the loss of oxygen. In biological systems the direct union of molecular oxygen with cellular metabolites has never been satisfactorily demonstrated although oxygen is, of course, the ultimate oxidizing agent in all aerobic organisms. While it is true that oxygen may be added to the molecule, as in the oxidation of an aldehyde to an acid, it is not molecular oxygen which is added, but, rather, oxygen which has its origin in some other source such as water or phosphate. In the case of the majority of the metabolites concerning whose physiological oxidation anything definite is known, the primary oxidation is effected by the removal of two hydrogen atoms (or two hydrogen ions and two electrons) through the agency of a specific dehydrogenase. It is with this hydrogen that oxygen eventually reacts, to form either water or hydrogen peroxide. The union of the liberated hydrogen with oxygen may be a direct one in the case of a relatively few dehydrogenases, such as certain flavoproteins whose activity leads to the formation of H_2O_2 . In other cases, the liberated hydrogen atoms, or hydrogen ions and electrons derived from them, are believed to be transported to molecular oxygen by a series of reversible oxidation-reduction systems. The

hydrogen is oxidized to water, and free energy is liberated. The molecular oxygen which takes part in oxidative reactions finally appears, therefore, only in the form of water, as the result of oxidation of hydrogen. No molecular oxygen enters directly into the formation of CO_2 ; the oxygen contained in this product of respiration was either present originally in the compound oxidized or was added to it, in the form of water or of phosphate, at some intermediary stage of oxidation.

Oxidation-reduction potential. An oxidation-reduction (O-R) system contains two chemically related components which are capable of reversible transformation by the transfer of one or more electrons (or of H-ions and electrons). The relationship between the reduced and oxidized components (frequently called the 'reductant' and 'oxidant' respectively) may be represented by the equation

reduced component \rightleftharpoons oxidized component + $n e$
where n represents the number of electrons (e) transferred. The oxidizing or reducing power of such a reversible system in relation to that of other similar systems depends on two main factors: (1) a capacity factor which is governed by the concentration or, more accurately, the 'activity' of the reactants, and (2) an intensity factor which is a fundamental property dependent upon the nature of the substances concerned. The intensity factor is the characteristic oxidation-reduction potential of the system and is represented by the symbol E_o in the equation

$$E_h = E_o + \frac{RT}{nF} \ln \frac{[\text{Oxidant}]}{[\text{Reductant}]}$$

where E_h is the potential (in volts) of an inert metallic electrode measured in a system of arbitrarily chosen ratio of [Oxidant] to [Reductant], and referred to the normal hydrogen electrode, at absolute temperature T . R is the gas constant, expressed in electrical units, n is the number of electrons transferred, and F is the faraday. E_o is the normal potential of the system at $pH = 0$, referred to the normal hydrogen electrode when $[Ox] = [Red]$. When the concentrations of oxidant and reductant are equal the ratio is unity and the logarithm zero; then $E_h = E_o$. The normal hydrogen electrode ($pH = 0$) has been arbitrarily assigned a potential of zero. On increasing the pH at constant temperature, the potential of the H electrode decreases by approximately 0.06 volt for each unit of pH ; at $pH 7.0$ its potential is -0.421 . Similarly, the potential of other systems may be affected by changes in pH if, for example, the ionization of the reactants is influenced by pH -changes. And since the determination of the O-R potentials of biological systems is usually made at pH levels other than $pH = 0$, it is necessary to modify the term E_o in the above equation in conformity with this practice and with the effect of pH -changes. The observed O-R potential of a given system depends, therefore, not only on the inherent tendency of the system to yield or accept electrons

and on the ratio of the concentration of the oxidant to that of the reductant, but also, quite frequently, on the pH. In the equation

$$E_h = E'_0 + \frac{RT}{nF} \ln \frac{[\text{Oxidant}]}{[\text{Reductant}]}$$

the term E'_0 represents the characteristic potential of the system at the designated pH and its value is equal to that of the observed potential (E_h) at this pH when $[\text{Oxidant}] = [\text{Reductant}]$. Values of E'_0 , measured at pH levels close to neutrality, have been determined for a considerable number of reversible biological systems; they vary from very negative values (e.g. -0.371 v for the system, hypoxanthine \rightleftharpoons xanthine at pH 7.0) to quite positive values (e.g. $+0.255$ v for the system, ferrous cytochrome C \rightleftharpoons ferric cytochrome C at pH 7.0). Lists of such values are recorded by Fischer (1939), by Oppenheimer and Stern (1939) and by Barron (1943b). Systems with more negative potentials are more reducing than those with more positive potentials. The H-electrode with a potential of -0.421 v at pH 7.0 represents a system of great reducing intensity; at the opposite extreme is the oxygen-electrode having a potential of $+0.810$ v at pH 7.0, representing a system of great oxidizing intensity.

It should be emphasized that in order that an oxidizing or a reducing solution may give a definite, stable potential two important conditions must be satisfied. In the first place, the oxidized and reduced forms must both be present in definite amounts; the potential of a pure oxidant or of a pure reductant is meaningless. Secondly, each of the two components must be capable of conversion into the other as the result of an infinitesimally small change in the equilibrium or static potential in one direction or the other. This means that the system must be thermodynamically reversible; only the potentials measured in such systems have any fundamental significance and only such systems play any significant role in the physiological transport of hydrogen and electrons. Reference to the chemical nature of some of the physiologically important transport systems will be made later. Meanwhile it may be stated that of the several systems concerned some are most easily recognized as carriers of H-atoms or of H^+ ions and electrons, whereas others such as cytochrome transport electrons only. In all cases, however, the catalytic role of the carrier systems in the respiratory process depends on the exchange of electrons.

The significance of O-R potentials in studies of the mechanisms of biological oxidation is twofold. In the first place, knowledge of the characteristic potentials of the several systems which take part in the transfer of electrons from the metabolites to molecular oxygen permits an evaluation of the possibility of reaction between two given systems and provides information as to the sequence in which the several systems may co-operate in electron-transfer. Under suitable condi-

tions it is possible that a system with a more negative potential will reduce a system having a more positive or higher potential. While it cannot be said that a system of higher potential will always oxidize a system of lower potential, a system of lower potential will not oxidize one of higher potential. The sequence of the interaction of the several O-R systems which constitute the respiratory mechanisms of living organisms is probably determined by many factors, one of which—obviously an important one—is the relationship existing between the characteristic potentials of the different reversible systems. But the fact that two O-R systems react with each other *in vitro* does not necessarily mean that they will also react *in vivo*. Considerations of this kind may impose serious limitations on the interpretation of the results of *in vitro* experiments in terms of intracellular reactions. Knowledge of the potentials of reacting systems has also been used in calculating the amount of free energy liberated at successive stages of the respiratory process. Suppose that a system of higher potential is reduced *in vitro* by one of lower potential, and that the difference between their characteristic potentials (E'_0), referred to the normal hydrogen electrode, is E (expressed in volts) when each system is half reduced (or oxidized). The free energy change ($-\Delta F$) is calculated from the equation $-\Delta F = nEF$, where n is the number of electrons transferred and F is the faraday (i.e. approx. 23060 calories).

Dehydrogenases. A dehydrogenase catalyzes the oxidation of a specific metabolite (AH_2) by causing it to give up hydrogen (or H^+ ions and electrons) to a suitable H-acceptor (B) which, thereby, becomes reduced: $AH_2 + B \rightarrow A + BH_2$. Many dehydrogenases have been shown to catalyze reactions which are thermodynamically reversible and which, as *isolated* reactions, can be represented by the following equilibrium:

reduced substrate \rightleftharpoons oxidized substrate + $2H^+ + 2e^-$. The enzyme not only activates the reduced form (AH_2) of the substrate as a H-donor, but it also activates the oxidized form (A) as a H-acceptor. A dehydrogenase-system represented by the equilibrium above is an oxidation-reduction system characterized by a definite O-R potential (E'_0), measurable *in vitro*, which depends upon the chemical nature of the two components and upon other factors such as pH. But the equilibrium is stable only if the ratio of the two components remains unchanged. It is unlikely that such an equilibrium can exist in the living cell because of the presence of other O-R systems, of lower or higher potential, which tend continuously to disturb the equilibrium by donating or accepting electrons.

Dehydrogenation of the reduced component (AH_2) of a reversible dehydrogenase-system can take place only if there is also present another O-R system of higher, more positive, potential, so that its oxidized component (B) can accept hydrogen or electrons from the reduced form of the first system. The reaction of

the two systems with each other is reversible and, in the absence of disturbing factors, will reach a dynamic equilibrium: $A H_2 + B \rightleftharpoons A + B H_2$, with the result that the oxidation of $A H_2$ is far from complete. The process of dehydrogenation of $A H_2$ can go to completion only if $B H_2$ can become a H-donor for another acceptor which is the oxidized component of an O-R system whose potential is higher than that of system B. In this way, through the mediation (as H^+ ion- and electron-carriers) of a series of O-R systems of gradually increasing potential (i.e. having increasing oxidizing intensities), the equilibrium, above, is constantly shifted to the right and the dehydrogenation of $A H_2$ progresses. Eventually the system represented by molecular oxygen, having a very high potential, comes into play and the transfer of hydrogen ions and electrons from the metabolite to O_2 is completed by a virtually irreversible series of reactions in which all of the free energy of the hydrogen is released. In such a series of reactions this energy is liberated in a step-wise manner and energy is made available to the cell at each step in an amount which depends on the difference of potential between the two systems which react with each other at that step. The total energy released in the several steps is equivalent to the energy liberated by the direct oxidation of the hydrogen to water by molecular oxygen.

On the basis of present knowledge of their activities most of the known dehydrogenases can be classified tentatively according to the method of disposal of the hydrogen which is liberated from the substrate as the result of the catalytic action. Several such methods are now recognized.

(1) The hydrogen is transferred directly to molecular oxygen, to form H_2O_2 , by a prosthetic group attached to the enzyme protein, as in the case of certain flavo-proteins such as d-amino acid oxidase and xanthine oxidase. The peroxide formed in the reaction is subsequently removed by catalase or, possibly, by peroxidase. Water is the final product.

(2) The hydrogen is oxidized to water through the direct mediation of the cytochrome system between the dehydrogenase system on the one hand and molecular oxygen on the other. It has been customary to include among the dehydrogenases reacting in this manner a few enzymes such as succinic dehydrogenase, lactic dehydrogenase of yeast, α -l(+)-glycerophosphate dehydrogenase of muscle, and two or three others. But in the case of succinic dehydrogenase it now appears that an additional mediator, possibly a flavo-protein, may intervene between the dehydrogenase and cytochrome.

(3) The hydrogen is transferred to molecular oxygen, to form water, through the mediation of a more complex series of oxidation-reduction systems, including one of the two co-dehydrogenases (coenzymes, pyridine nucleotides), a flavoprotein, cytochrome, and cytochrome oxidase, functioning in the order named. Dehydrogenases reacting in this manner are more

numerous than all other types and are further differentiated, according to the nature of the necessary pyridine nucleotide, into three groups: (a) those which require diphosphopyridine nucleotide (coenzyme I), (b) those which require triphosphopyridine nucleotide (coenzyme II), (c) one or two dehydrogenases which exhibit no specificity with respect to the pyridine nucleotide. Members of group (a) are considerably more numerous than those of the other groups. Schlenk (1942) has listed a number of these dehydrogenases together with their essential coenzymes.

In aerobic (respiratory) systems the hydrogen liberated from certain metabolites can be regarded as being transported in one direction to molecular oxygen by one or other of the above methods or by some similar method. The results are: (1) the metabolite is oxidized by the removal of hydrogen, and (2) the hydrogen is oxidized by union with oxygen. In glycolytic systems where anaerobic conditions prevail or where the supply of oxygen is insufficient to enable the respiratory processes to meet the demands of the cell for energy, the hydrogen released from the metabolite is not oxidized by molecular oxygen but may instead, be taken up by another, different, metabolite which is activated as a hydrogen-acceptor by its own specific dehydrogenase and thus becomes reduced. This means that two different dehydrogenase systems each containing an enzyme and its specific substrate react with each other in such a manner that the reduced component ($A H_2$, below) of one system is oxidized to the oxidized component (A) while the oxidized component (B) of the other, while the latter is, of course, reduced to $B H_2$. Linked reactions of this kind have been demonstrated *in vitro* in the presence of one of the pyridine nucleotides (Co) which functions in the transfer of hydrogen, as illustrated by the following equations:

The net result is expressed as follows:

In anaerobic glycolysis, and in fermentation in general, the oxidation of one compound is always accompanied by the reduction of another. Molecular oxygen does not, of course, take part in the reaction.

An important example of a coenzyme-linked reaction is the reduction of pyruvic acid by phosphoglyceraldehyde to form lactic acid, the end product of glycolysis in muscle.

Reaction C is a summation of reactions A and B but it is enabled to proceed only through the mediation of the coenzyme which functions as an oxidation-reduction system in the transfer of hydrogen. [It should be stated that reaction A, as written above, is a simplification of the following reactions, D and E, in which 1,3-diphospho-d-glyceric acid is first formed and is later dephosphorylated enzymatically in the presence of adenosine diphosphate (ADP), to yield 3-phospho-d-glyceric acid and adenosine triphosphate (ATP).

Reaction D is the oxidative (or, more accurately, the oxido-reduction) reaction of alcoholic fermentation and of glycolysis in which an *energy-rich phosphate bond*, in this case a carboxyl phosphate bond, is created in position 1 of 1,3-diphospho-d-glyceric acid. The latter compound serves as a donor of phosphate and energy in reaction E for the replenishment of the reservoir of ATP which is needed for the formation of hexosediphosphate in an earlier stage of glycolysis. An examination of reaction D reveals the fact that it is, in reality, a coupled oxidation—phosphorylation in which an energy-rich carboxyl phosphate (acyl phosphate) is formed from an aldehyde group. The enzymes catalyzing reactions D and E are, respectively, phosphoglyceraldehyde (or triose) dehydrogenase and transphosphorylase; both enzymes have recently been prepared in the form of crystalline proteins, but in each case the crystalline protein can exercise its catalytic activity only in the presence of its specific coenzyme, namely Co I in the first case and adenosine polyphosphate in the second.]

In addition to the H-transporting systems mentioned above, it is not unlikely that other reversible O-R systems may function in a similar manner. To two such systems, namely, oxaloacetate \rightleftharpoons malate (catalyzed by malic dehydrogenase) and fumarate \rightleftharpoons succinate (catalyzed by succinic dehydrogenase) Szent-Györgyi has attributed a pre-eminent rôle in transporting hydrogen from cellular metabolites to cytochrome, and he has suggested that the essential function of the four-carbon dicarboxylic acids in the tissues is to act in this catalytic manner. Space does not permit a discussion of the physiological significance of these compounds; an appraisal of their importance is to be found in the recent review of Krebs (1943).

Cytochrome and cytochrome oxidase. Let us turn now from the dehydrogenases, which can be regarded as functioning at one end of the respiratory chain, to the O-R systems at the other end which are concerned with making molecular, inactive, oxygen available to the cell for the oxidation of hydrogen liberated from cellular metabolites. These latter systems constitute the cytochrome system consisting of the enzyme cytochrome oxidase and three hemochromogen-

like pigments, cytochromes a, b, and c. Each of these four compounds is believed to be a reversibly oxidizable protein-complex containing an iron-porphyrin as its prosthetic group, oxidation and reduction being effected, in each case, by the exchange of an electron of the iron atom ($\text{Fe}^{++} \rightleftharpoons \text{Fe}^{+++} + e$). The discovery of the tetrapyrrol grouping in the structures of these compounds has served further to emphasize its special biological importance; for it is present also in chlorophyll (in which magnesium replaces iron), in hemoglobin, in catalase, in peroxidase and in other compounds of physiological significance. The tetrapyrrol structure appears, therefore, to be necessary not only for securing solar energy to be used in biological activities of all kinds, and for transporting molecular oxygen from the lungs to the tissues of higher animals, but also for its utilization in energy-liberating reactions within the tissues themselves.

Warburg was the first to realize the importance of the iron-porphyrin structure in intracellular oxidation. Since a large proportion, sometimes 90 per cent or more, of the normal oxygen-consumption of cells of many types can be blocked by small amounts of cyanide, Warburg was led, several years ago, to suspect that the enzyme chiefly responsible for the catalysis of oxygen-consumption in aerobic cells is a compound containing a heavy metal such as iron. Later, when he observed that the oxygen-consumption of the cells was greatly diminished in the presence of carbon monoxide if the system was kept in the dark, but that respiration was not affected by CO when the cell-suspension was exposed to light, he suggested that the enzyme is a conjugated protein whose prosthetic group is an iron-porphyrin; for the only substances known to form light-dissociable compounds with CO are those which contain an iron-porphyrin as a part of their structure. Still later, by means of an ingenious photochemical method, Warburg was able to obtain, as he believed, an accurate picture of the absorption-spectrum of the CO-compound of the enzyme, without even attempting to remove the enzyme from the cells. The spectrum so obtained resembled very closely the spectra of the CO-compounds of several heme-containing substances such as pyridine- and nicotine-hemochromogens; these latter spectra were determined not only by the conventional methods but also by the same photochemical procedure as had been employed with cell-suspensions. It is not possible, in this short section, to include a description of Warburg's experimental procedures and observations; nor is it necessary to consider the theoretical aspects of his interpretations. He was, however, led to the definite conclusion that the enzyme concerned with cyanide-sensitive respiration in living cells is an iron-porphyrin-protein complex; in spite of subsequent criticism of his methods and interpretations, his conclusion as to the chemical nature of the enzyme has never been seriously challenged.

To this enzyme Warburg gave the name "the oxygen-transferring enzyme"; and, in the early formulations

of his ideas as to its mode of action, he attributed to it the function of "oxygen-activation," as a result of which oxygen is enabled to oxidize directly the metabolites of the cell. This conception differed fundamentally from that of Wieland which emphasized the dominant role of the dehydrogenases as the activating agents responsible for the consumption of oxygen. Wieland regarded the liberated, "activated" hydrogen as undergoing direct oxidation by molecular oxygen.

As a result of experiments initiated some twenty years ago by Keilin, it became clear that neither the dehydrogenase systems, alone, nor an agent of the type of Warburg's enzyme, alone, can catalyze the oxidation of cellular metabolites by molecular oxygen. Keilin showed that both types of catalyst are essential components of a more complex oxidative system than that postulated either by Warburg or by Wieland. In 1886 MacMunn had observed in muscle and other tissues certain pigments which he named myo- and histo-hematin; until 1925, however, they had failed to arouse any widespread interest. In that year Keilin announced the discovery of three heme-containing pigments, in aerobic cells and tissues of many kinds, to which he gave the names cytochrome a, b, and c; the c-component appeared to correspond, spectroscopically, to the modified pigment of MacMunn. These pigments were later shown by Keilin to function as mediators linking the dehydrogenase systems of the cell with the system composed of molecular oxygen (O_2) and an enzyme, formerly known as indophenol oxidase but now generally recognized as cytochrome oxidase. This enzyme resembles very closely Warburg's "oxygen-transferring enzyme"; but, instead of oxidizing directly a large number of cellular compounds, in the manner suggested by Warburg, it is restricted in its action to the oxidation of the ferrous iron of one of the cytochromes by O_2 .

The three pigments together with cytochrome oxidase constitute a system which transports electrons to O_2 , and, by doing so, makes possible the oxidation of the hydrogen liberated from cellular compounds which are activated by specific dehydrogenases. Though all four components of the cytochrome system are believed to be iron-porphyrin-protein compounds, the oxidase differs from the cytochromes in several respects. For example, though the oxidase reacts directly with O_2 , cytochromes a and c are not autooxidizable except in the extreme ranges of pH; cytochrome b reacts directly with O_2 and, to some extent therefore, may be independent of the oxidase. Moreover, cytochrome oxidase in its ferrous form combines with CO to form a light-dissociable compound, and in its ferric form with cyanide; as a result of either combination, the activity of the enzyme is inhibited, apparently by interference with the transfer of electrons. On the other hand, the positions of the characteristic absorption bands of all three cytochromes are unaffected by the presence of either CO or cyanide, an observation which has been interpreted to mean that none of the three cytochromes combines with either CO or cyanide

(Keilin and Hartree (1939)). But since each of these substances can inhibit respiration in cells which contain cytochrome, it is concluded that the cytochromes themselves must function only as systems which transfer electrons between cytochrome oxidase on the one hand, and, on the other, the dehydrogenase itself, as in the case of dehydrogenases of class 2, or a flavoprotein, as in the case of dehydrogenases of class 3. Two other cytochromes, a_3 and b_2 , have been described, but their properties and functions will not be discussed here.

Upon their release from the metabolites, or more usually from a flavoprotein which has served as an intermediary hydrogen-carrier, the "metabolic" hydrogen-atoms are ionized and yield H-ions. The electron lost by each H-atom is believed to be taken up in succession by the trivalent iron of the components of the cytochrome system, in other words by four iron-porphyrin compounds, reducing each in turn ($Fe^{+++} + e \rightleftharpoons Fe^{++}$). Each cytochrome on yielding an electron to the ferric iron of the adjacent member of the chain becomes reoxidized and is then in a position to accept another electron. Finally, the divalent iron of the oxidase itself, the last member of the series, is oxidized to the trivalent state by O_2 . The mechanism of this oxidation is still only imperfectly understood; without attempting to discuss the theoretical aspects of the problem, it is sufficient to state that the interaction of O_2 and the ferrous form of cytochrome oxidase in an aqueous medium facilitates the transport of electrons by the cytochrome system as a whole and makes possible the oxidation of metabolic hydrogen to water. It is unlikely that all four compounds necessarily function in the cyanide-sensitive respiration of aerobic cells of all types, since some types of cells are known to lack one or other of the three cytochromes. The sequence in which the four compounds participate in the transfer of electrons to O_2 is believed to be as follows: cytochrome b—cytochrome c—cytochrome a—cytochrome oxidase. This conclusion is based upon considerations of the O-R potentials of the several systems.

Only one of the pigments, namely cytochrome c, has been obtained in soluble form; the others are so intimately bound to the insoluble material of the cells that they have resisted all attempts to separate them from this material. The c-component has, however, been highly purified. The purest preparation obtained by Theorell had a heme-iron content of 0.43 per cent and molecular weight of 13000. The structure and amino acid content of this product have been described by Theorell and Åkesson (1941). It is of considerable interest that approximately 30 per cent of the total nitrogen (including the porphyrin nitrogen) of cytochrome c is represented by the essential amino acid lysine, a compound which has not yet been identified with any specific reaction or function in living organisms. No other protein is known to contain such a large proportion of lysine.

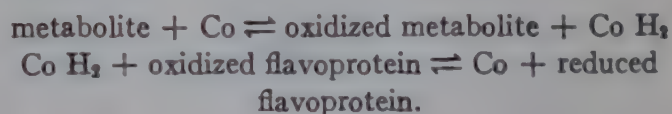

Until quite recently no one had succeeded in obtain-

ing a clear solution of cytochrome oxidase free from insoluble cellular particles. Using procedures such as high-speed centrifugation and ultrasonic radiation, Haas (1943) obtained from pig-heart a water soluble preparation with a slight Tyndall effect, containing an enzyme, having cytochrome oxidase activity, whose properties, like those of indophenol oxidase, appeared to be identical, in several respects, with those of Warburg's enzyme. In later studies, Haas (1944) separated the enzyme into two fractions, one of which proved to be more heat-stable and more soluble than the other; both components were found to be necessary for the oxidation of cytochrome c by molecular oxygen.

The pyridine nucleotides and flavoproteins. Reference has been made to the fact that many dehydrogenases depend for their activity upon the co-operation of a coenzyme which is either diphosphopyridine nucleotide (cozymase, coenzyme I) or triphosphopyridine nucleotide (coenzyme II). The coenzyme is regarded by some workers as a prosthetic group bound to a specific activating protein or "apodehydrogenase," the two components together forming a "pyridinoprotein" having the properties of a specific dehydrogenase. Others prefer to look upon the activating protein itself as the dehydrogenase and the coenzyme as one of its substrates. At the moment of catalysis the metabolite and the coenzyme are both bound to the activating protein, and hydrogen is transferred from the metabolite to the coenzyme, with the result that the former is oxidized and the latter reduced. Unless, however, the reduced coenzyme can be reoxidized, the extent of oxidation of the metabolite is negligible since it is limited by the small amount of coenzyme present. One method of reoxidation of the coenzyme, as in coenzyme-linked oxidation-reduction reactions, has already been mentioned. A second method is of greater significance in respiration and is concerned with the catalytic role of certain flavoproteins which oxidize the reduced coenzyme by transferring its labile hydrogen to O_2 by way of the cytochrome system in the manner already described. The coenzymes themselves do not react directly with O_2 ; the only known physiological agents which can effect their oxidation by O_2 , *in vitro*, at adequate speeds are two specific flavoproteins. One of these, known as cytochrome c-reductase (CR) and found, so far, only in yeast, is a dehydrogenase which specifically catalyzes the oxidation of reduced coenzyme II ($Co II H_2$) by oxidized cytochrome c. In this way CR may link the cytochrome system with the dehydrogenase systems which depend upon $Co II$. The other flavoprotein, named diaphorase or coenzyme-factor, is present in animal tissues as well as in yeast and bacteria and has been shown to catalyze the oxidation of $Co I H_2$ (and possibly $Co II H_2$) by methylene blue *in vitro*. In an aerobic system the resultant leucomethylene blue is reoxidized by O_2 , so that a relatively small amount of the dye enables the physiological carriers to transport relatively large amounts of metabolic hydrogen to O_2 . The direct reaction of diaphorase with the cytochrome

system has not been satisfactorily demonstrated; however, the facts that diaphorase can oxidize $Co I H_2$ and that the oxidation, in tissue slices, of the substrates of several dehydrogenases which require $Co I$, is sensitive to cyanide, suggest that diaphorase constitutes at least part of the link between $Co I H_2$ and the cytochrome system. The nature of the other part of the link is still unknown. Straub in 1939 obtained from pig-heart a soluble flavoprotein having all the catalytic properties of the coenzyme-factor, the activity of which had hitherto been associated with insoluble particles in the tissue extracts. The activity of Straub's flavoprotein was such that under optimum conditions each molecule of the enzyme catalyzed the aerobic oxidation of ca. 8000 molecules of $Co I H_2$ per minute by carriers such as methylene blue. Since this flavoprotein also oxidizes $Co II H_2$, it may be the factor which is mainly concerned with the oxidation of both coenzymes in animal tissues. But the reaction of the reduced flavoprotein with the cytochrome system under physiological conditions still awaits further clarification.

The reactions involving the dehydrogenase, the pyridine nucleotide and the flavoprotein can be summarized as follows:

The reduced flavoprotein (i.e. either diaphorase or CR) is eventually reoxidized by oxidized cytochrome; in the case of CR this oxidation appears to be effected directly by oxidized cytochrome c, whereas in the case of diaphorase another carrier, as yet unknown, may intervene between the flavoprotein and the cytochrome system. The oxidation of the hydrogen transported by the flavoprotein is, eventually, made possible by the mediation of the cytochrome system in the manner previously described. The oxidation product is water.

Only a brief reference to the chemical nature of the coenzymes and flavoproteins is possible here. Both pyridine nucleotides (coenzymes) are, in reality, dinucleotides containing two mononucleotides united through their phosphoric acid residues. $Co II$ contains a third phosphoric acid residue but is, otherwise, similar in structure to $Co I$. One of the mononucleotides in each coenzyme is adenylic acid (adenosine-5'-phosphate); the other mononucleotide contains nicotinic acid amide, d-ribose and phosphoric acid united in this order (i.e. nicotinamide-d-riboside-5'-phosphate). The flavoproteins are compounds in which a specific activating protein is bound to a prosthetic group which may be either a mononucleotide, flavin phosphate, (i.e. the 5'-phosphate of 6, 7-dimethyl, 9-d-ribityl isoalloxazine) as in cytochrome c-reductase, or a dinucleotide, flavin-adenine dinucleotide, containing flavin phosphate and adenylic acid united through their phosphoric acid residues. The dinucleotide is present in a number of flavoproteins, including diaphorase.

The following reactions illustrate the manner in which hydrogen, released from cellular metabolites through the agency of specific dehydrogenases, is transferred to diaphorase by way of coenzyme I.

be oxidized by a flavoprotein which Green (1944) has shown to be present in rat-kidney. It is generally believed that the flavoprotein oxidases which react directly with molecular oxygen are responsible for a large proportion of the cyanide-insensitive respiration of aerobic cells. The yellow enzyme of Warburg and Christian, 1932, has the distinction of being the first flavoprotein to have been isolated from living cells (yeast) but no significant physiological role has, as yet, been attributed to it; indeed, there is reason for believing that this product, now known as the "old yellow enzyme" may have resulted, during its extraction from yeast, from the denaturation of some other flavoprotein such as cytochrome c-reductase. In any event, no one has succeeded in demonstrating the presence of any flavoprotein in animal tissues which is identical with Warburg and Christian's yellow enzyme.

The preceding brief description of some of the oxidative catalysts of living organisms does not, of course, embrace all oxidases which are believed to exist in living cells. But the oxidation systems which have been discussed appear to constitute a recurring pattern in organisms of widely different types. These respiratory enzyme systems are made up of two main components: (1) a specific catalytic protein whose function is concerned with the release of H-atoms from the oxidizable substrate, (2) a number of reversible oxidation-reduction systems which transport either the hydrogen atoms themselves or electrons which are derived from them, from the substrate to molecular oxygen. The potentials of these systems become more positive as the oxygen-end of the respiratory chain is approached. In some cases only a single O-R system intervenes between the substrate and O_2 , as in the oxidation of α -amino acids by a specific flavoprotein. In other cases two different O-R systems function as carriers, as for example in the oxidation of succinic acid by succinate dehydrogenase, in which an unknown carrier and the cytochrome system are concerned. In still more complicated respiratory systems at least three different types of O-R systems may take part in the transport of hydrogen and electrons, namely, one of the pyridine nucleotides, a flavoprotein, and the cytochrome system. The transport of hydrogen by the pyridine nucleotide and by the flavoprotein in such a system is frequently formulated as a bivalent process, two H-atoms being transferred simultaneously. But the investigations of Michaelis and his co-workers [see Michaelis, 1940] have indicated that every oxidation or reduction is step-wise in character; in each step one electron is transferred, the intermediary substance formed in the first step of a bivalent reaction being a free radical, a semi-oxidized or semi-reduced form. When applied to dehydrogenase reactions in biological systems this principle of free radical formation is of particular interest; for it provides an explanation of the manner in which an apparently bivalent reaction can be linked with the univalent transfer of electrons by the cytochrome system. At each step along the respiratory

path leading from the metabolite to O_2 free energy may be made available to the cell, the amount of energy depending upon the relative oxidation-reduction potentials of the adjacent O-R systems which react with each other in the transport of electrons. Ball (1944) has made some calculations of the possible free energy released in the successive steps. Of the total free energy liberated during the passage of one electron from the pyridine nucleotide to O_2 by way of flavoprotein and the cytochrome system, approximately 75 per cent is liberated during the passage of the electron through the cytochrome system to O_2 .

Other oxidases. Some plants and certain lower forms of animal life contain oxidases which are copper-protein compounds and do not, therefore, fall into any of the special categories discussed in this chapter, though their activity is, in some respects, similar to that of dehydrogenases in general. They catalyze the direct oxidation of their substrates by molecular oxygen, the copper of the enzyme acting as a prosthetic group in the transfer of electrons from the substrate to O_2 . The copper-containing enzymes include those which oxidize ascorbic acid, mono- and polyphenols. Higher animals do not appear to possess enzymes of this kind.

Unclassified oxidases include, among others, the enzymes uricase, which oxidizes uric acid to allantoin; amine oxidase; diamine oxidase, which oxidizes certain diamines and histamine with the liberation of ammonia and the formation of an aldehyde and H_2O_2 ; luciferase, which is concerned with the phenomenon of luminescence in luminous bacteria and other organisms; fatty acid dehydrogenase which is present in the liver and muscle of the rat and oxidizes certain higher fatty acids.

Glutathione. This tripeptide, glutamyl cysteinyl glycine, discovered in 1921 by Hopkins, is almost universally distributed in the intracellular fluids of animal tissues as well as in plants, yeasts and many bacteria. Of all the known cellular compounds containing the sulphhydryl group, apart from the proteins, glutathione is probably the most widely distributed in living cells; for this reason and because it is capable of reversible oxidation to the disulphide form, many attempts have been made to demonstrate its activity as a hydrogen-transporting system in cellular oxidations. It is doubtful, however, whether such a function can be attributed to the compound; for all attempts to demonstrate the full reversibility of the change from the reduced (sulphydryl) form to the oxidized (disulphide) form have failed. The potential of the system appears to be determined solely by the reduced form; it is unlikely that a substance having these properties can play any important role in the physiological transport of hydrogen or electrons in respiratory systems. Moreover, the fact that it is present in living cells almost entirely in the reduced form suggests either that the reduction of its oxidized form is much more rapid than the oxidation of its

reduced form, or that there is no cycle of reduction and oxidation.

Other functions of glutathione have, however, been more firmly established. It acts, for example, as a coenzyme in the transformation of methyl glyoxal to lactic acid by the enzyme glyoxalase. But, in the present discussion, its role in maintaining the —SH groups of enzymes is of greater interest. The presence of the sulphhydryl group in several oxidizing enzymes, as well as in several proteolytic and other enzymes, has been shown to be necessary for their activity (Bersin 1935, Hellerman 1937, Barron and Singer 1945). In view of the fact that oxidizing agents in the cell tend to inhibit the activity of —SH enzymes, it is probable that one of the main functions of glutathione in cellular systems is concerned with the continuous reactivation of the —SH enzymes. Its capacity to bring about such a reactivation, through its powerful reducing action, has been demonstrated in many experiments. Glutathione appears, therefore, to influence cellular oxidations in an indirect rather than in a direct manner.

It must be emphasized that much of our knowledge of the oxidizing systems present in living organisms has been acquired in studies of the activity of extracts and of "reconstructed" systems of many kinds. But the ultimate aim is an understanding of reactions and processes in the living, undamaged cell, an organized, heterogenous structure of great complexity. Studies of reconstructed systems representing fragments of cellular structures cannot possibly reveal the full significance of cellular organization in relation to metabolic processes.

Relation of vitamins to oxidative catalysts. At least three water-soluble vitamins bear a close relationship to intracellular oxidative catalysts. Nicotinic acid in the form of its amide is a constituent of the pyridine nucleotides, and riboflavin enters into the structure of the flavoproteins; these two vitamins appear, therefore, to be necessary for the formation of compounds which are primarily concerned with the transport of hydrogen from cellular metabolites to O_2 . A third vitamin, thiamin, is believed to function in the cell, in the form of thiamin pyrophosphate, as a coenzyme in the enzymic transformation of α -keto acids such as pyruvic and α -keto-glutaric acids, in reactions involving decarboxylation, oxidation, condensation, CO_2 -fixation, dismutation. The role of thiamin pyrophosphate (co-carboxylase) in intermediary metabolism has been discussed in several recent reviews, including those of Ochoa (1942) and Barron (1943a).

The liberation of CO_2 in decarboxylation reactions accounts for a large proportion of the CO_2 formed during the oxidation of carbohydrates; similar reactions are probably responsible for the formation of CO_2 during the oxidation of fatty acids, though the pathways by which fatty acids are oxidized have been less thoroughly explored. Decarboxylations, in general, are not accompanied by any appreciable energy-change;

the energy liberated in biological oxidations is believed to originate very largely in the oxidation of hydrogen. Decarboxylation is, nevertheless, an important reaction; for it reduces the size of the carbon-skeleton of a compound and, in this way, creates a new molecular species which can be activated by its own specific oxidase.

The relation of other vitamins to oxidative reactions in animal tissues is much less firmly established than is that of the three vitamins mentioned above. The reversible oxidation of ascorbic acid *in vitro* and the unsaturated nature of the molecule of vitamin A suggest that these vitamins may play some part in oxidative reactions *in vivo*, but in neither case is there any convincing experimental evidence of such a role in animal tissues. On the other hand, recent studies have indicated that vitamin E is related in some manner to the oxidative systems of skeletal muscle. Houchin and Mattill (1942) have observed that dystrophic muscle removed from vitamin E-deficient animals, as compared with muscle from normal animals, has a considerably higher respiration *in vitro*, as measured by oxygen-consumption. Biopsy experiments on the E-deficient rabbit demonstrated that the oral administration of α -tocopherol or the parenteral administration of tocopherol phosphate lowered the high initial respiration of the muscle toward normal values. In other experiments, the *in vitro* respiration of dystrophic muscle-slices was significantly lowered by α -tocopherol phosphate added to the medium; the succinic acid oxidase activity of dystrophic muscle, *in vitro*, was similarly reduced by added α -tocopherol phosphate. Tocopherol itself had no effect in either case. The full significance of these results is not yet clear; while they suggest, as Houchin points out, that tocopherol phosphate acts as a "brake" on the oxidative mechanisms of skeletal muscle, nothing is known of the manner in which the effect is exercised.

The coupling between oxidation and phosphorylation in biological systems. Recent studies of the coupling of oxidation with phosphorylation have assisted greatly in explaining at least one mechanism by which energy liberated in oxidative reactions can be stored temporarily for subsequent utilization by the organism. Equation D on page 327 represents a reaction in which the aldehyde group of 3-phosphoglyceraldehyde is oxidized to a carboxyl group while, at the same time, an acyl phosphate, namely 1,3-diphosphoglyceric acid is formed. In this oxido-reduction step, sometimes called the oxidative reaction of glycolysis (see fig. 150 $\frac{1}{2}$)*, inorganic phosphate enters into the formation

* The writer is greatly indebted to Dr. V. R. Potter for permission to reproduce this figure from his paper, published in 1944, on "Biological Energy Transformations and the Cancer Problem." Commenting on this figure, Potter (1944) states in part: "The metabolism of any given tissue is the resultant of the balance between the various enzymes that are responsible for

of an energy-rich phosphate bond as the result of an oxidative (energy-yielding) process. Potential energy is thus accumulated. [Ordinary phosphoric acid ester linkages, as in glycerophosphate, involve only a relatively small energy-change (3000 calories or less), in contrast with *energy-rich linkages* where the energy-change is of the order of magnitude of 8000 to 12000 calories. Linkages of the latter type occur in adenosine di- and tri-phosphates, creatine phosphate, arginine phosphate, phosphopyruvic acid, and acyl phosphates.] The change in free energy (ΔF) in going from carbonyl (aldehyde) to carboxylate (acid) at pH 7 is stated by Kalckar (1944) to be -29000 calories. Of this amount, $+12500$ calories are used for the coupled reduction of Co I to Co I H_2 (equation D); the remaining -16500 calories are available for synthesis (i.e. the creation of an energy-rich phosphate bond at position 1), approximately -11000 calories being stored as unstable acyl

O
||
R—C—O—PO₃H₂

phosphate (R—C—O—PO₃H₂) in 1, 3, diphosphoglyceric acid (DPG). In reaction E on page 327 (see also fig. 150½) DPG reacts with adenosine diphosphate (ADP) to form 3-monophosphoglyceric acid and adenosine triphosphate (ATP). In this reaction an energy-rich phosphate bond is transferred, by a specific transphosphorylase and without dissipation of energy (ca. 11000 calories), from position 1 in DPG to its new position in ATP. This reaction is one of two reactions, in the glycolytic series, which serve to replenish the store of phosphate-bond energy in ATP. As Meyerhof (1944) points out, the phosphorylation of ADP to ATP in this reaction represents a net gain in free energy, while the Co I H_2 (produced in reaction D, page 327) is reoxidized in the reduction of one mole of pyruvic to lactic acid (reaction B, page 326). The second glycolytic reaction in which an energy-rich phosphate bond is formed in ATP is the reaction between phosphoenolpyruvic acid and ADP to yield pyruvic acid and ATP. The formation of the energy-rich phosphate bond in phosphopyruvic acid is the result of an intramolecular change from 3-phosphoglyceric acid to 2-phosphoglyceric acid, followed by dehydration to yield 2-phosphoenolpyruvic acid. Lipmann (1941) has calculated the ΔF of the reaction, phosphoenolpyruvate + H_2O = pyruvate + phosphate, to be 11250 calories. This amount of energy is sufficient to create an energy-rich phosphate bond in ATP when phosphoenolpyruvate reacts with ADP. [This latter reaction, unlike all the other reactions encountered in the transformation of glycogen into lactic acid, has, until very recently, been considered to be irreversible and is indicated as such in figure 150½.]

each of the reactions in the figure. Certain of the starting materials which are stored in the cells or must be brought to the cells are shown at the periphery of the figure. These materials include glucose, oxygen, glycogen, fat and various vitamins which serve as building blocks for coenzymes."

However, Lardy and Ziegler (1945) have demonstrated that the reaction is reversible, provided that K^+ ions are present.]

Thus, in two reactions of the glycolytic series, the store of ATP is replenished; this is, of course, desirable and necessary because the ATP reserve is depleted in earlier reactions of glycolysis which lead to the formation of fructose-1-6-diphosphate.

The formation of energy-rich phosphate bonds has also been shown to take place as the result of the coupling of phosphorylation with aerobic oxidations. For example, Lipmann (1942) isolated acetyl phosphate, the primary product of the oxidation of pyruvate, by *Lactobacillus Delbrückii*, to CO_2 and acetate. Acetyl phosphate contains an energy-rich phosphate bond which can phosphorylate adenylic acid to form ATP. Moreover, Umbreit and others (1942, 1943) have made the interesting observation that the autotrophic sulphur bacillus, *Thiobacillus thio-oxidans*, can store the energy of sulphur-oxidation in the form of energy-rich phosphate bonds of ATP, and that this energy can be used anaerobically in the dark for the assimilation of CO_2 in this organism.

Recent investigations have indicated that another source of energy for the formation of energy-rich phosphate bonds in ATP is to be found in the aerobic oxidative cycle of reactions, known as the Krebs or isocitric acid cycle, by which pyruvic acid (or carbohydrate by way of pyruvic acid) is oxidized to CO_2 and water. From figure 150½ it is apparent that one complete cycle liberates 3 moles of CO_2 , representing the oxidation of all three carbon atoms of pyruvic acid; 5 pairs of H-atoms are also liberated in the cycle and are ultimately oxidized via the cytochrome system to yield water and energy. From the recent work of Ochoa (1943) it now appears that part of this energy (ca. 60 per cent) is used to form energy-rich phosphate bonds. He calculated that for each of the 5 atoms of oxygen consumed in the oxidation of the 5 pairs of H-atoms, 3 moles of inorganic phosphate, on the average, are esterified to form adenosine polyphosphate. In figure 150½ the five groups of triple arrows connecting the Krebs cycle with the ATP system are intended to express this relationship. Ochoa's results, in addition to other evidence, would seem to indicate that during the oxidation of pyruvate in the Krebs cycle, intermediary phosphorylated compounds are formed, containing energy-rich phosphate bonds. But, apart from acetyl phosphate, identified by Lipmann as the primary product in the oxidation of pyruvate (by lactic acid bacteria), no other phosphorylated intermediary compound which could arise in the Krebs cycle has, as yet, been identified. Potter (1944), commenting on figure 150½ which is reproduced from his paper, states: "The figure does not show the exact mechanisms for the aerobic phosphorylations in the Krebs cycle because these are not known, but each of the di- and tricarboxylic acids shown probably occurs in phosphorylated form."

Krebs (1943) has pointed out that some 8 or 9 amino acids can yield, directly or indirectly, either pyruvic acid or oxaloacetic acid or α -keto-glutaric acid. These three acids are intermediaries in the isocitric acid cycle, and, therefore the oxidation of the amino acids from which they can arise is facilitated by the cyclic mechanism. Since the 8 or 9 amino acids may constitute a considerable fraction of some proteins (e.g. 43 per cent of casein), the Krebs cycle may represent an important pathway for the oxidation of protein in some animal tissues; if so, it is to be expected that the oxidation of the amino acid derivatives by way of the cycle will yield phosphate-bond energy to be stored in adenosine polyphosphate.

It is probable that energy-rich phosphate bonds are also formed during the oxidation of lipids. Lardy and others (1945) have shown that the oxidation of the endogenous lipid-reserve of bovine spermatozoa is accompanied by the esterification of inorganic phosphate to form a labile ester which appears to be ATP. This is the first report of the fixation of phosphate during the oxidation of lipids. According to Lehninger (1945), the oxidation of fatty acids by enzymes present in liver-homogenates is activated by ADP or ATP or by a compound which can form ATP by donating phosphate to adenylic acid. He has suggested that preliminary phosphorylation of the carboxyl group of the fatty acid by ADP or ATP to form an acyl phosphate is an obligatory step in the oxidation of the acid, and that at a later stage of oxidation the energy-rich phosphate bonds are returned to the ATP-reservoir.

The utilization of phosphate-bond energy. In the preceding paragraphs some of the metabolic reactions leading to the formation of energy-rich phosphate bonds have been discussed briefly. ATP contains two such bonds, each of which represents an accumulation of ca. 11000 calories; ADP contains one bond of this type. The adenylic system consisting of adenylic acid, ADP and ATP, constitutes a coenzyme whose function appears to be concerned only with trans-phosphorylations but not with the uptake or direct release of inorganic phosphate. On the left-hand side of figure 150 $\frac{1}{2}$ several paths are indicated by which the phosphate-bond energy of ATP is believed to be utilized in the performance of work of different kinds. Various aspects of the problem of the generation and utilization of phosphate-bond energy have been discussed in several recent reviews, including those of Lipmann (1941), Meyerhof (1944), Kalckar (1942, 1944) and Potter (1944).

The relation of ATP to muscular contraction is discussed in another chapter of this book; therefore, only a brief reference to this subject is made here. The breakdown of ATP in muscle was found, several years ago, to be closely associated in point of time with the act of contraction, an observation which led to the suggestion that the energy necessary for contraction is derived directly from ATP. During the past few years this view has gained widespread acceptance.

But the mechanism by which the energy of ATP is made available to the muscle is almost completely unknown. When Engelhardt and Lyubimova discovered, in 1939, that in the myosin fraction, i.e. the contractile element, of muscle there is present in relatively large amounts an enzyme, adenosine triphosphatase (ATP-ase), which liberates inorganic phosphate from ATP (see Engelhardt, 1942), interest in the relationship between ATP and function became intensified. Moreover, the observation of Bailey (1942, 1944) that Ca^{++} ions activate the ATP-ase of myosin (the enzyme apparently hydrolyzing ATP only to the ADP-stage), coupled with observations of others that the stimulation of muscle is accompanied by the release of Ca^{++} ions, would seem to indicate an association between the activity of the enzyme and function. But no proof of such an association has, as yet, been obtained. If the enzyme acts merely as a hydrolytic agent, liberating inorganic phosphate from ATP, the potential energy accumulated in the energy-rich phosphate bond would be dissipated as heat. A more probable mechanism for the utilization of the phosphate-bond energy of ATP in contraction would involve, as a preliminary step, an intermediary coupling of the dephosphorylation of ATP with the phosphorylation of myosin, in order to maintain the phosphate group potential at a high level. So far, however, no experimental evidence of any such transfer of phosphate to myosin has been obtained, though the guanidine group of arginine in the protein would seem to provide a suitable point of attachment of phosphate to form an energy-rich bond. Apart altogether from these considerations, there remains the unsolved problem of the nature of the mechanisms which enable the muscle to transform chemical energy into mechanical work.

If the immediate energy for contraction is, indeed, derived from ATP, the resynthesis of the compound can be effected by the transfer of energy-rich phosphate bonds from creatine phosphate. This compound (CP) serves as a reservoir of phosphate-bond energy and reacts with adenylic acid and with ADP to yield ADP and ATP, respectively. In these reactions phosphate-bond energy is transferred to the adenylic system, and free creatine is formed. For the subsequent resynthesis of CP from creatine, phosphate-bond energy is drawn, in turn, from the ATP reservoir which is maintained at an essentially constant level by the acquisition of phosphate from energy-rich phosphorylated intermediary compounds formed in the glycolytic and oxidative reactions previously discussed. The special value of the reservoir of energy in creatine phosphate is associated with the fact that only by interaction between CP and the adenylic system can the phosphate-bond energy of CP be released; muscle is not known to contain an enzyme which can hydrolyze CP with the formation of free creatine and free phosphate, and therefore it would appear that there is no possibility of the dissipation

of the energy of creatine phosphate by direct hydrolysis. Under conditions of normal energy-requirements, the total reserve of phosphate-bond energy is not depleted, since it is in dynamic equilibrium with the glycolytic and oxidative sources of energy.

Pathways of carbohydrate breakdown and the Pasteur effect. It has been the main purpose of this section to consider, in broad outline, the principal oxidizing enzyme systems of living cells, as understood at the present time, in relation to the liberation and utilization of free energy. No attempt has been made to discuss in detail the intermediary chemical reactions of carbohydrate metabolism. The accompanying figure illustrates mechanisms which have been proposed to explain the degradation of carbohydrate under anaerobic and under aerobic conditions. These and other mechanisms are discussed critically in several recent reviews, including those of Meyerhof (1942), Evans (1942), Dorfman (1943), Krebs (1943) and Barron (1943a), and in recent papers of Sacks (1943, 1944).

Another problem which can only be mentioned here is that of the mechanism of the Pasteur effect. This effect is most accurately defined as the inhibition, by oxygen, of the accumulation of the products of the anaerobic breakdown of carbohydrate in organisms and tissues which are equipped with mechanisms enabling them to release energy from carbohydrate either by fermentation or by oxidation. An example of such a tissue is skeletal muscle which is able to obtain free energy from glycogen either by fermentation (in this case "glycolysis"), with the formation of lactic acid,

or by oxidation to CO_2 and water. Glycolysis appears to be an emergency mechanism which operates when the supply of oxygen is insufficient to enable the respiratory mechanisms to meet the energy-demands of the organism, during, for example, a short period of hard work when a relatively large amount of lactate accumulates in the blood and a correspondingly large oxygen-debt is incurred. Under conditions of prolonged but moderate muscular effort, on the other hand, the anaerobic mechanism appears to operate only during a brief period at the beginning of exercise; during this preliminary period of adjustment the oxygen-consumption rises to a new equilibrium-level which remains relatively constant during the period of moderate work, after which it drops quickly to the resting level. The blood-lactate which had risen slightly, as the result of glycolysis, during the initial period of adaptation returns to nearly normal levels shortly after the attainment of the new equilibrium-level of oxygen-consumption, indicating that as soon as the oxygen supply has become adjusted to the increased demands for energy the anaerobic mechanism no longer operates. In other words, oxygen, when present in adequate amounts, suppresses glycolysis. This is the Pasteur effect. In the case of intensive short-term effort the adaptation is too slow to supply oxygen in adequate amounts and the organism must depend upon the anaerobic mechanism for its supply of free energy. The mechanism of the Pasteur effect is discussed by Dixon (1937), Burk (1939), Johnson (1941), Lipmann (1942).

CHAPTER XXXIII

THE CARRIAGE OF CARBON DIOXIDE BY THE BLOOD

The total carbon dioxide content of blood means the amount of CO_2 which can be extracted from a given volume of blood by exposure to a vacuum after the addition of acid. The results are usually expressed as volumes per cent (v.p.c.) by which is meant cc. of CO_2 (measured at S.T.P.) per 100 cc. of blood. The methods of Van Slyke and his coworkers are now most commonly used for the measurement of CO_2 in blood and other fluids. In Van Slyke's manometric apparatus a known volume of blood is acidified and subjected to a partial vacuum in which CO_2 and other gases are rapidly extracted. The gases are then compressed to a known volume and their pressure measured. The CO_2 is removed by introducing NaOH and the pressure at the same volume is again measured. From the change in pressure the amount of CO_2 can be calculated. By such a method then, it is found that human blood normally contains 50 to 60 v.p.c. of CO_2 , the venous blood usually containing 5 to 10 v.p.c. more than the arterial.

It was first shown by Pflüger (1864) that, if whole blood were very thoroughly evacuated, all the CO_2 could be removed without the addition of acid. On the other hand, all the CO_2 in plasma could not be removed by vacuum alone. After very thorough evacuation the addition of acid or of red blood corpuscles allowed the liberation of more CO_2 . These facts suggested that, in plasma, CO_2 is present mainly as bicarbonate; for on exposure to a vacuum NaHCO_3 loses a part of its CO_2 according to the equation,

To liberate the CO_2 in Na_2CO_3 it is necessary to add acid. These results suggested, too, that the red cells contain something which can act as an acid. We now know that the hemoglobin in the red cells is an amphoteric electrolyte and hence capable of acting as an acid.

The amount of dissolved CO_2 in blood can be calculated from its solubility coefficient in blood (table 28), when the pressure of carbon dioxide with which the blood is in equilibrium is known (p. 338). The dissolved CO_2 consists in part of carbonic acid (H_2CO_3). Although the actual amount of H_2CO_3 is extremely small (being only

about 0.1 per cent of the dissolved CO_2) it is of great importance. When H_2CO_3 enters the blood, which is a slightly alkaline solution, it combines with base to form bicarbonate (BHCO_3) until an equilibrium is reached between the three forms of CO_2 :

The relative amounts of these three forms at equilibrium depend upon the pH of the solution and can be calculated from the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_1 + \log \frac{(\text{BHCO}_3)}{(\text{CO}_2) \text{ dissolved}^1}$$

TABLE 28
Solubility of CO_2 in physiological fluids at body temperature

FLUID	ABSORPTION COEFFICIENT ²
Water.....	0.545
Plasma.....	0.510
Red cells.....	0.44
Whole blood.....	0.48

pK_1 is a composite constant which in normal plasma has a value of about 6.1. The pH of plasma is normally about 7.4. Hence we may write:

$$7.4 = 6.1 + \log \frac{\text{Bicarbonate } \text{CO}_2}{\text{Dissolved } \text{CO}_2^1}$$

or

$$\frac{\text{Bicarbonate } \text{CO}_2}{\text{Dissolved } \text{CO}_2} = \frac{20}{1}$$

If the pH of the plasma is abnormal this ratio will, of course, be different.

The interior of the red cell is more acid than the plasma. Consequently, the ratio of bicarbonate to dissolved CO_2 will be smaller. Furthermore,

¹ At a given temperature (H_2CO_3) is a constant fraction of the dissolved CO_2 and hence does not require separate representation in the formula.

² Cubic centimeters CO_2 (measured at S.T.P.) dissolved in 1 cc. fluid at a pressure of CO_2 of 760 mm. Hg.

since the water content of the red cell is less than that of plasma, the amount of dissolved CO_2 will be less too. For these two reasons then, at the same tension of CO_2 the cells contain *less* total carbon dioxide than the plasma. Yet, as we shall soon see, the red cells play the dominant rôle in the transport of carbon dioxide.

THE RÔLE OF HEMOGLOBIN IN CARBON DIOXIDE TRANSPORT

When carbon dioxide enters the blood from the tissues it combines with water to form H_2CO_3 . This reaction is relatively slow in most solutions with a pH close to neutrality. In the blood, however, the reaction is catalyzed by an enzyme, carbonic anhydrase, which is found in the red cell but not in the plasma. The H_2CO_3 is thus formed within the cells. Nearly all of the H_2CO_3 thus formed then combines with base to form bicarbonate. The base available for combination is that which is already combined with weaker acids, mainly proteins, which are displaced by carbonic acid according to the equation,

Hemoglobin is used as the example in this equation because it does, in fact, furnish directly and indirectly, the greater part of the base used. It does so for a number of reasons. In the first place, it comprises about three-quarters of the total protein in blood. Secondly, it holds in combination an even greater proportion of the base held by weak acids in the blood, because it has so many weak acid groups in its molecule. Thirdly, it has the remarkable property of changing its acid strength with its degree of oxygenation. When the blood is in the tissues it loses its oxygen and the hemoglobin becomes a weaker acid and able to yield more base to carbonic acid. In the lungs the hemoglobin is oxygenated and becomes a stronger acid. This assists in displacing carbonic acid from combination with base and in turning it out of the blood. Figure 151 shows the titration curves of oxyhemoglobin and hemoglobin. It will be seen that at the same pH oxyhemoglobin is combined with more base than is hemoglobin, i.e., oxyhemoglobin is the stronger acid.

That hemoglobin behaved in this peculiar way was first suggested by Christiansen, Douglas and Haldane (1914), who investigated the *carbon dioxide dissociation curve* of reduced and oxygenated whole blood. As in the construction of an

oxygen dissociation curve, samples of oxygenated or reduced whole blood are brought into equilibrium in a series of saturating vessels, called tonometers, with different pressures of CO_2 . The CO_2 contents of the equilibrated bloods are then determined by analysis and plotted against the corresponding gas tensions. Christiansen, Douglas and Haldane found that the curve for oxygenated blood was lower than that for reduced blood. In other words, reduced blood could carry more CO_2 at the same tension of CO_2 than oxygenated blood (fig. 152). For many years it was

FIG. 151. Curves to show the amounts of base (K) bound by oxygenated and reduced hemoglobin at varying pH. The slopes of the curves represent the buffer values, in terms of the equivalent of base required to cause unit pH increase (from Peters and Van Slyke, *Quantitative Clinical Chemistry*, Vol. 1, 1932, from data of Hastings, Van Slyke, Neill, Heidelberger and Harington).

thought that this phenomenon was due entirely to the change in acid strength of hemoglobin on oxygenation. Reduced hemoglobin, being a weaker acid, would yield more base to carbonic acid and hence, at equal pressures of CO_2 , more bicarbonate would be formed. It now appears, however, that fifty per cent or more of this greater CO_2 -combining power of reduced blood is due to the greater power of reduced hemoglobin to combine directly with CO_2 (see p. 340).

Leaving aside the question of how the greater CO_2 -combining power of reduced blood is effected, let us consider the physiological importance of the phenomenon. By examining figure 152, it will be seen that if the blood, represented by point A

on the curve, took up 5 v.p.c. of CO_2 , from the tissues and no reduction of the hemoglobin occurred, the tension of CO_2 in the blood would rise by about 14 mm. Hg. If, however, about 6 v.p.c. of O_2 are lost from the capillary blood (as indicated by point V) the extra CO_2 can be taken

FIG. 152. Carbon dioxide dissociation curves of fully reduced human blood (upper solid line) in presence of hydrogen, and fully oxygenated human blood (lower solid line), in presence of air. Volumes of CO_2 along the ordinates; CO_2 tension along the abscissae. Line AVB is the so-called physiological dissociation curve of CO_2 , i.e., as a result of the reduction of hemoglobin the relation of volumes of CO_2 to CO_2 tension is indicated at points along this line and not along the lower curve for oxygenated blood. At A (arterial point) are indicated the volume and tension of CO_2 in arterial blood. Point B indicates the conditions in fully reduced blood. Point V (venous point) represents the degree of reduction of hemoglobin which normally occurs in the body during the passage of the blood through the systemic capillaries. The position of the line AVB varies with the respiratory quotient, moving to the right or left, respectively, with a rise or fall in the R.Q. Its position in the figure corresponds to a respiratory quotient of about 0.8. The interrupted line below is the CO_2 dissociation curve for oxygenated dog's blood. (Modified from Christiansen, Douglas and Haldane.)

on with a rise of only 7 mm. Hg in the CO_2 tension. As the change in CO_2 tension is minimized, so too is the change in the pH of the plasma, because at the lower pressure of CO_2 less free carbonic acid is present. In the lungs the reverse reactions occur. Here oxygenation of the hemoglobin reduces the CO_2 -combining power of the blood, and a smaller fall in CO_2 pressure is effective in removing the excess CO_2 .

The dominant rôle of the red cells in CO_2 transport can be further demonstrated by contrasting the CO_2 dissociation curves of *separated* plasma and *true* plasma. The latter is constructed by exposing whole blood to different pressures of CO_2 , and then separating the plasma and analyzing it for CO_2 ; the former by equilibrating plasma in the absence of red cells (fig. 153).

It is apparent that the curve for *separated* plasma is much flatter than that of *true* plasma which signifies that much larger changes in CO_2 pressure and pH accompany a given change in CO_2 content in *separated* plasma. Evidently separated plasma is not as well buffered as true plasma.

FIG. 153. Comparison between the CO_2 dissociation curves of blood and of separated and true plasma from the same blood. (After Evans, redrawn from data by Joffe and Poulton.)

The greater buffer power of true plasma must be due to the red cells. We know, however, that base ions, e.g., K^+ and Na^+ cannot pass from the red cell into the plasma, because the red cell membrane is impermeable to cations with the exception of H^+ . Consequently, the red cells must increase the buffer power of the plasma indirectly. They do so by means of the *chloride shift* or *Hamberger phenomenon*.

If CO_2 is added to whole blood and the corpuscles and plasma are analyzed separately, it will be found that:

- (1) The bicarbonate content of both plasma and corpuscles has increased.
- (2) The chloride content of the corpuscles has increased.
- (3) The chloride content of the plasma has decreased.
- (4) The metallic cation content of the corpuscles and plasma has not changed.

(5) The water content and volume of the corpuscles has increased.

The reverse changes occur when CO_2 is removed from blood by evacuation. Evidently, there is a transfer of the chloride from plasma to cells when CO_2 enters the blood, and the reverse process when CO_2 leaves the blood; hence the name, chloride shift. A simple qualitative explanation of this phenomenon can be given. When CO_2 enters the blood more HCO_3^- is formed in the corpuscles than in the plasma because they contain more available base for neutralizing H_2CO_3 . These excess HCO_3^- ions tend to diffuse out into the plasma, but, owing to the electrostatic attraction of the cations within the cells, can only do so if an equal number of Cl^- ions enter to take their place. Thus HCO_3^- from the cells enters the plasma in exchange for Cl^- which enters the corpuscles. This process will continue until an equilibrium is reached which has been found to agree (very nearly) with the distribution required by Donnan's theory of membrane equilibria (p. 103). This requires the following relations:³

$$\begin{aligned} \frac{[\text{H}^+]_{\text{cells}}}{[\text{Cl}^-]_{\text{cells}}} &= \frac{[\text{H}^+]_{\text{plasma}}}{[\text{Cl}^-]_{\text{plasma}}} \\ \frac{[\text{H}^+]_{\text{cells}}}{[\text{HCO}_3^-]_{\text{cells}}} &= \frac{[\text{H}^+]_{\text{plasma}}}{[\text{HCO}_3^-]_{\text{plasma}}} \end{aligned}$$

or

$$\frac{[\text{H}^+]_{\text{plasma}}}{[\text{H}^+]_{\text{cells}}} = \frac{[\text{Cl}^-]_{\text{cells}}}{[\text{Cl}^-]_{\text{plasma}}} = \frac{[\text{HCO}_3^-]_{\text{cells}}}{[\text{HCO}_3^-]_{\text{plasma}}}$$

The phenomenon can, in fact, be explained very precisely in terms of the Donnan theory. When CO_2 enters the blood the ratio $\frac{(\text{HCO}_3^-)_{\text{cells}}}{(\text{HCO}_3^-)_{\text{plasma}}}$ increases because more base is available in the cells. Similarly because the buffer power of plasma is less than that of the cells $\frac{(\text{H}^+)_{\text{plasma}}}{(\text{H}^+)_{\text{cells}}}$ increases. The Cl^- of the plasma must now pass into the cells in exchange for HCO_3^- until the ratios are again equalized at a new level. Since the new ratio is a higher one, the number of osmotically active particles in the cells must now be higher than in the plasma. Consequently, water enters the corpuscles to equalize the osmotic pressures of the corpuscles and plasma and the volume of the corpuscles increases. If stasis of blood occurs during the withdrawal of blood from

a vein, an abnormal amount of CO_2 may accumulate and the relative volumes of corpuscles and plasma may be appreciably altered. Hence stasis is undesirable when the blood is required for purposes where the relative volumes of corpuscles and plasma must be measured, e.g., in the estimation of blood volume.

THE EVOLUTION OF CARBON DIOXIDE IN THE LUNGS

The pressure of CO_2 in the alveoli is kept by respiratory activity at a lower level than it is in venous blood; hence CO_2 diffuses from the blood into the alveoli. This disturbs the equilibrium between the three forms of CO_2 and causes reactions to proceed in the direction indicated below:

It has been known for a long time that the reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$ is inherently a slow one. It is known too that the blood spends only about one second in the capillaries of the lung and about the same time in the capillaries of active tissues. The velocity constants of these reactions in solutions other than blood are known too, and it can be calculated that if blood had not certain peculiar properties, the time which it spends in the lungs would scarcely allow the escape of 10 per cent of the CO_2 which we know does escape. Rapid loading and unloading of CO_2 by the blood is accomplished in two ways. The first, which has been mentioned already, is the action of the enzyme, carbonic anhydrase, which accelerates enormously, in either direction, the reversible reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$. As carbonic anhydrase is found only in the red cells and not in the plasma, we may deduce that the rapid changes in CO_2 content occur primarily in the red cells while the plasma comes more slowly into equilibrium with the cells, perhaps after the blood has left the capillaries. Carbonic anhydrase is found in a few other locations besides red blood corpuscles. It is found in the pancreas where it may play some part in the secretion of pancreatic juice which is rich in bicarbonate. It is found also in small quantities in sperm and in muscle where its function is obscure.

The other mechanism for the rapid combination and dissociation of CO_2 in blood is the direct combination of CO_2 with hemoglobin. This reaction does not go through the stage of carbonic acid and is very rapid. For many years past the existence

³ In applying the Donnan equilibrium to the red cell the only cation which can be regarded as diffusible through the red cell membrane is the H^+ ion.

of such a compound has been generally denied. Recent experiments, however, make it appear that about twenty-five per cent of the CO_2 liberated in the lungs under normal resting conditions has been carried in the blood in direct combination with hemoglobin. Nevertheless, the total amount of CO_2 in the blood combined in this way is small; probably it never amounts to more than from 8 to 10 per cent of the total CO_2 . But the fact that reduced hemoglobin combines with more CO_2 than does oxyhemoglobin gives the compound an enhanced importance in the transport of CO_2 ;

FIG. 154. Upper curves, showing the proportions of the difference in CO_2 capacity of reduced and of oxyhemoglobin which is due to the higher carbamino content of reduced hemoglobin. The shaded area represents the proportion due to carbamino CO_2 . Lower curves, showing the negligible effect of a rise in CO_2 tension upon the carbhemoglobin content of blood. (After Ferguson and Roughton, modified.)

it accounts for from 20 to 25 per cent of the gas freed in the lungs.

Carbon dioxide does not combine with the hemoglobin molecule in the same way that O_2 and CO do. It apparently combines with an NH_2 group to form a so-called carbamino-acid. Hence, one name suggested for this compound is hemoglobino-carbamic acid (Hb-NHCOOH). Another name less descriptive but possessing the virtue of brevity is carbhemoglobin.

Carbamino-compounds of CO_2 with amino-acids are well known and the technic of estimating these simpler compounds has been adapted for determining carbhemoglobin. Other forms of combined CO_2 , such as NaHCO_3 , can be precipitated as BaCO_3 by the addition of alkaline BaCl_2 . The barium salts of the carbamino-acids are soluble and remain in the supernatant fluid after centrifuging. The affinity of HB

for CO_2 diminishes with pH, and with strong acidification all the CO_2 dissociates off. Consequently, the Van Slyke technic for estimating total CO_2 can be applied to the supernatant fluid to measure the carbhemoglobin.

An increase in the CO_2 pressure of the blood should, *per se*, cause the formation of a greater amount of carbhemoglobin, but since an increase in CO_2 pressure is always accompanied by an increased acidity, which lowers the affinity of Hb for CO_2 , variations in CO_2 pressure over physiological ranges have actually little effect on the carbhemoglobin content of the blood. That is to say, the dissociation curve of carbhemoglobin is practically flat over physiological ranges of CO_2 pressure. The main factor of physiological importance in displacing CO_2 from Hb is oxygenation of the Hb (fig. 154).

SUMMARY

About 5 per cent of the total CO_2 in blood is physically dissolved. Two to ten per cent, depending on the degree of oxygenation of the hemoglobin, is combined directly with hemoglobin (carbhemoglobin). The remainder is present as bicarbonate and, as such, is combined with base which has been yielded to H_2CO_3 by the weak acids of the blood; the most important of these is hemoglobin.

The CO_2 -combining power of reduced blood is greater than that of oxygenated blood, (1) because reduced hemoglobin is a weaker acid than oxyhemoglobin; and (2) because reduced hemoglobin can combine directly with more CO_2 to form carbhemoglobin that can oxygenated hemoglobin.

Base yielded by hemoglobin participates indirectly in the carriage of CO_2 by the plasma by means of the *chloride shift*. Base within the cells neutralizes the Cl^- ions which enter the red cells, thereby leaving base in the plasma free to neutralize HCO_3^- ions.

As the blood passes through the lungs it loses a small part of its total CO_2 (i.e., about 10 per cent). The elimination of CO_2 is accomplished with minimal change in pH and in CO_2 tension by the concurrent oxygenation of the blood which decreases the CO_2 -combining power of the blood in the two ways mentioned above.

The transfer of CO_2 , to and from the blood while it is in the capillaries, can be accomplished in less than one second, because (1) carbonic anhydrase catalyzes the slow reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$ and (2) because the formation and dissociation of carbhemoglobin is inherently rapid.

CHAPTER XXXIV

THE CONTROL OF RESPIRATION; PERIODIC RESPIRATION; DYSPNEA

THE LOCATION OF THE NERVOUS CENTERS OF THE RESPIRATORY MECHANISM. SPONTANEOUS ACTIVITY OF THE RESPIRATORY CENTER

It is customary and convenient to speak of the collections of nerve cells in the brain stem which discharge impulses to the muscles of respiration as the *respiratory center*. But the use of the term should not be taken to imply that the controlling nervous elements are in any sense a compact circumscribed mass or confined to a closely restricted area. Section through the brain at any level anterior to the upper border of the pons does not alter significantly the respiratory rhythm. But sections at various levels behind this cause pronounced disturbances in respiration. After cutting through the medulla behind the tip of the calamus scriptorius all breathing ceases. The many neurons whose integration constitute what is referred to as the respiratory center lie, therefore, over a relatively extensive area between the upper border of the pons and the lower third or so of the medulla oblongata. They are scattered at different levels through the formatio reticularis of these parts of the brain stem.

The classical experiments of Markwald (1887) form the basis of our knowledge of the location of the nervous structures controlling respiration. He described powerful and prolonged tonic inspiratory movements or "cramps" which supervened after bilateral section of the vagus nerves and division of the brain stem immediately behind the posterior colliculi. He concluded that a center inhibitory to inspiration was located in the latter situation, but that the vagi had also an inhibitory action, consequently the inspiratory "cramps" appeared only after vagal influence had been abolished as well. Markwald's observations were confirmed shortly afterwards by other experimenters. The subject was taken up in recent years by Lumsden, who found that the prolonged inspiratory movements occurred only if the section passed through the pons a few millimeters behind its anterior border and occurred whether or not the vagi were divided. The inspiratory cramps or *apneuses*, as Lumsden preferred to call them, last for several seconds. He postulated their dependence upon an *apneustic* or *inspiratory*

center at the level of the striae accousticae, which was dominated normally by an inhibitory or *pneumotaxic center* situated in the upper part of the pons. The duty of the latter center was, through its inhibitory influence, to transmute the apneustic movements into the rhythmical movements characteristic of normal respiration. After section of the brain stem behind the striae accousticae the respirations consisted of a series of gasps occurring at relatively long intervals. Lumsden concluded that these represented the activity of a primitive *gasping center* situated in the lower part of the medulla from which the two higher centers had evolved. It was considered to be of little importance in higher animals.

Lumsden's results have been confirmed in the main by Stella and by Pitts, Magoun and Ranson. Stella, however, found in contradiction to Lumsden that section through the pons (i.e. separation of the pneumotaxic center) did not result in apneusis unless the vagal influence was abolished also (see fig. 155). The results of Pitts and his associates are in essential agreement with those of Stella. They found that animals decerebrated through the upper part of the pons maintained a normal type of respiration which responded in the usual way to chemical and peripheral nerve stimulation so long as the vagi were intact, but immediately developed apneustic respiration and a complete cessation of rhythmical movements when the vagi were severed. The apneustic center is therefore under a double inhibitory influence either one of which is capable of converting the apneustic type of respiratory to the rhythm of normal or nearly normal respiration. The vagal impulses influencing the apneustic center are initiated by the stretch of the lung towards the latter part of the inspiratory phase of normal breathing (see p. 345).

The apneuses, like normal respirations, are affected powerfully by the CO_2 tension of the blood being increased in depth by having the animal breathe an air mixture containing a high concentration of CO_2 and reduced in depth, or prevented from occurring, by carbon dioxide lack (see p. 350). According to Stella, the pneumotaxic center is

bilateral but its connections with the apneustic center are mainly homolateral, i.e., uncrossed.

Pitts, Magoun and Ranson describe the respiratory center in the cat, which they locate in the reticular formation of the medulla, as consisting of an inspiratory and an expiratory division. The *inspiratory center* overlies the cephalic four-fifths of the inferior olive (fig. 156).¹ It is identified with the apneustic center of Lumsden. When stimulated a maximal co-ordinated inspiration results, involving both diaphragm and thorax. If stimulated during apneuses, the magnitude of the inspiratory movement is increased; if stimulated during an interval between apneuses an apneustic

ciprocal inhibition of one center upon stimulation of the other can be demonstrated. The similarity in the effects of stimulation of the expiratory center and of the central end of the vagus, namely, inhibition of inspiration and of apneusis, has led Pitts and his colleagues to the conclusion that the vagal respiratory effects are mediated through the expiratory center. The influence of the pneumotaxic center is probably exerted in the same way. (See also Bernthal.)

The respiratory center is connected with the motor neurones of the phrenic and intercostal nerves in the cervical (C. 3, 4 and 5) and upper thoracic segments of the cord (T. 2-6) by descend-

FIG. 155. Showing apneusis. Section of the brain stem along a plane passing dorsally immediately behind the posterior colliculi; and ventrally 2.5 mm. below the upper border of the pons. Between x and z the vagi were blocked by cold. Time: 2 sec. (After Stella.)

movement is produced. The *expiratory center* lies dorsal to and slightly anterior to the cephalic end of the inspiratory center. Electrical stimulation within this area causes expiration; if stimulated during inspiration or during apneusis these movements are inhibited. Regular respirations—inspiration alternating with expiration—are induced by rhythmical stimulation of the inspiratory center; expiration then occurs passively. Rhythmical stimulation of the expiratory center also produces regular respiration, spontaneous inspirations then alternating with the expiratory movements. Intimate connections exist apparently within the centers and between the two. Re-

¹ It is probable that the center is similarly located in man. Finley has described a case of respiratory failure in which a lesion was found post mortem in this situation.

FIG. 156. Dorsal view of lower brain stem of cat showing location of pneumotaxic (Pn.), inspiratory (Insp.) and expiratory (Exp.) centers. ing tracts which run in the anterior columns and in the ventral part of the lateral columns of the spinal cord.

The spontaneous activity of the respiratory center has been a subject of interest to physiologists for many years. Some investigators, such as Coombs and Pike, and Schafer, have denied that the center is capable of spontaneous activity, maintaining that afferent impulses, especially those set up in the lung by the stimulus of stretch and conveyed by the vagus, and those initiated from proprioceptors in the respiratory muscles and travelling by the posterior nerve roots, were essential. However, the results secured within recent years by means of improved methods of investigation leave little reason to doubt that, in

certain species at least, the brain stem continues to discharge impulses to the respiratory muscles after all or nearly all afferent paths have been severed. For example, rhythmical bursts of impulses can be recorded from the central stump of the phrenic nerve of a decerebrate animal after section of the vagi, glossopharyngeal and other cranial nerves entering the pons and medulla, and division of the spinal cord below the level of the 7th cervical segment. Such an extensive operation would certainly interrupt all important afferent paths including those from the carotids and the aortic arch. It is not to be supposed, of course, that the respirations would be normal after such a radical procedure, for even if not essential for maintaining the activity of the center, affer-

spread through the rich interneuronal connections of the centers and enter a circus (see circus movement, p. 201), through which expiratory neurones are inhibited and inspiratory neurones excited. Thus, an apneustic inspiration is established which persists until the circus is broken, which it is after a time, as a result of reduced excitability of the neurones concerned, due in turn to the cessation of pulmonary ventilation during the apneustic period.

The grading of the strength of the contractions of the inspiratory muscles is apparently brought about by (a) alterations in frequency of the twitches of the component muscle units and (b) recruitment and derecruitment of the individual muscle units.

FIG. 157. Comparison of potential wave rhythm and rhythm of respiratory movements. (After Adrian and Buytendijk.)

ent nerve influences are of the utmost importance in the regulation of that activity and the production of the normal respiratory rhythm. Evidence for the automaticity of the respiratory center of a cold blooded species has been secured by Adrian and Buytenijk. They succeeded in recording rhythmical action potentials originating in the vagal lobes of the excised brain stem of the goldfish; the potential changes had the same range of frequency as the respiratory movements (fig. 157).

The spontaneous respiratory activity is apparently dependent primarily upon the inspiratory center. There is no evidence that impulses are discharged spontaneously from the pneumotaxic center. Pitts and his colleagues suggest that the pneumotaxic center is excited from the inspiratory center, that a proportion of the impulses discharged from the latter region ascend to the pontine center from whence impulses descend to the expiratory center; a discharge of inhibitory impulses is transmitted from the latter to the inspiratory center. A similar explanation is offered for the production of apneustic respiration. When the inspiratory center is cut off from the pontine and vagal influences it is postulated that impulses

Voluntary control. Emotional influences

That the respirations are under voluntary control for short periods of time is common knowledge. This control, though we are scarcely conscious of it in most instances, is being exerted in numerous ways in the ordinary affairs of daily life such as in speaking, swallowing (p. 478), laughing, blowing, coughing, sucking, etc. But the power of the will to inhibit respiration is strictly limited. The breath can be held for only a brief space (about 45 seconds) before automatic or involuntary control asserts itself; the inhibitory influence is overriden and the muscles of respiration contract despite all one's efforts to "hold the breath" (see also p. 350). The nerve elements giving origin to the voluntary impulses are probably in the motor area of the cerebral cortex. Stimulation of area 6a in monkeys accelerates the respirations; area 6b is inhibitory.

The respirations may be effected profoundly by impulses arising in higher cerebral centers as a result of various emotional or other mental states e.g., fear, grief, surprise, interest, amusement, etc.

Reflex control

Hering-Breuer reflexes. The importance of afferent impulses from the lungs in the control of respiration was first pointed out in 1868 by Hering and Breuer, who showed that inflation of the lungs arrested inspiration, expiration then ensuing, while deflation inhibited expiration and brought on inspiration. These are reflex effects, mediated through the afferent fibers of the pulmonary vagi, for they are abolished after these nerves have been divided. In ordinary breathing the inflation re-

deflation of the lungs is required, as can be produced in the laboratory by forcible compression of the chest, by collapse of the lungs through the production of a pneumothorax, or by sucking air from the trachea.

Head, in a later study of these reflexes in Hering's laboratory, isolated a slip of the diaphragm and recorded its action during distension and deflation, respectively, of the lungs. When the trachea was clamped towards the end of a normal inspiration the muscle slip immediately relaxed

FIG. 158A. Records of impulses discharged over vagus nerve during inflation of lung. Spinal cat, single fiber preparation. Inflation of the lungs by pump. Movement of signal line directly proportional to inflation. A, inflation = 65 cc., maximum frequency, 80 per second; B, inflation = 115 cc., maximum frequency, 120 per second; C, inflation = 230 cc., maximum frequency, 250 per second. (After Adrian.)

FIG. 158B. Showing discharge of impulses over a single fiber of the phrenic nerve during artificial respiration (wavy line) in a curarized animal. (After Partridge.)

flex alone comes into play, thus checking, at the end of an inspiration of the usual duration, further distension of the lungs. When the inhibitory vagal influence is abolished by cutting the nerves the respiratory rate, as might be expected, is slowed, for the inspiratory phase then continues for a longer period before it gives place to expiration. As mentioned on page 342 inspiratory movements of such length as to abolish rhythmical respiration follow if the inhibitory influence emanating from the pontine (pneumotaxic) center is excluded as well. The corresponding deflation reflex does not apparently play a part under ordinary conditions (Adrian, Partridge). In order to elicit it, extreme

and the inspiratory movement ceased. Blocking the trachea at the end of expiration called forth a powerful inspiratory movement; sucking air from the lungs caused a tonic contraction of the diaphragm.

Adrian approached the problem by recording during the phases of respiration the action potentials passing up a single afferent vagal fiber. The frequency of the impulses was found to vary with the degree of stretch of the lung, being highest when lung inflation was greatest (i.e., at the end of the inspiratory phase) and lowest when deflation was more nearly complete (i.e., towards the end of expiration) (fig. 158A). The receptors

which, as intimated above, are sensitive to a stretching force, are thought to be situated in the walls of the alveolar ducts, the most distensible parts of the lung structure. They adapt slowly (p. 806), for a stream of impulses continues to ascend the nerve with relatively little reduction in frequency while inflation of the lung is maintained.

There are many interesting points to be considered in connection with the effect of vagus nerve impulses on the rhythm of respiration, two of which may be mentioned here. (1) It was observed by Stewart, Pyke and Guthrie that the rhythm of respiration in a case which had been resuscitated from brain anemia was the same as that of the artificial respiration which was given during the resuscitation process. (2) It is easy to show, when phrenic impulses (fig. 158B) are recorded by a valve amplifier in a curarized animal, that the rhythm of the respiratory center comes into phase with that of the artificial respiration. The phrenic impulses coincide with the inspiratory phase of artificial respiration as long as the vagi are intact. This correlation is lost when the vagi are cut.

CAROTID AND AORTIC REFLEXES

Heymans and Heymans made the surprising discovery in 1927 that respiratory reflexes could be elicited from the aortic area. This discovery and the brilliant researches of Heymans and his associates, in the years following, on the corresponding role played by the structures in the region of the carotid bifurcation opened a new field in the physiology of respiration, and a fresh outlook upon the vexed question of respiratory control. Many preconceptions and misconceptions have been swept aside. A more detailed description of these areas has been given in Chapter XXVII where their functions in the control of the vascular system were discussed.

The carotid and aortic areas each contain two types of receptors; one type (pressoreceptors) responds to mechanical, the other (chemoreceptors) to chemical stimulation. The pressoreceptors situated among the collagenous fibers in the wall of the carotid sinus and in the wall of the aortic arch, are stimulated by a stretching force, as by a rise in arterial blood pressure. The chemoreceptors are contained in small gland-like structures—the *carotid* and *aortic bodies* (p. 240). The respiratory reflexes initiated from these two types of receptors are contrary in their effects.

Stimulation of the pressoreceptors inhibits respiration, an abrupt rise in blood pressure such as follows the injection of adrenaline causing respiratory arrest (apnea). Excitation of the chemoreceptors increases the rate and depth of breathing. Both types of reflex are abolished by section of the supplying nerves (sinus or aortic).

Though of the utmost importance in the control of the circulation, the *pressoreceptors* do not appear, in mammals at least, to serve any respiratory function under physiological conditions. There is no circumstance of a physiological nature under which the inhibition of respiration is caused by a rise in blood pressure or by the stimulation of these receptors in any other way. Nor is it apparent that such a reaction would serve any useful purpose. That they give a respiratory response when very strongly stimulated appears to be accidental and without physiological significance. They may possibly represent the vestige of a mechanism which was of value in some aquatic ancestral form and to which the mammalian body has fallen heir.

The *chemoreceptors* are stimulated by oxygen lack, but not, according to Schmidt and Comroe, until the oxygen tension of the arterial blood reaches a relatively low level—probably a little below 70 mm. Hg in man. At this tension the arterial blood is about 92 per cent saturated with oxygen. An anoxemia of this grade is approximately equivalent to that caused by breathing an air mixture containing 18 per cent of oxygen or by ascending to an altitude of 4000 feet (fig. 160).

The chemoreceptors are less sensitive still to carbon dioxide. When, for example, the carotid body is isolated from the general blood stream (effect upon the respiratory center thus eliminated), but its nerve supply retained, and then perfused with a solution containing CO_2 , the smallest change in CO_2 tension which causes an appreciable change in respiration is around 10 mm. Hg. When, on the other hand, the reflex effect is abolished by denervation of the carotid area, a change in CO_2 tension of only 3 mm. Hg in the blood supplying the respiratory center is sufficient to induce hyperpnea (Schmidt, Dunkley and Dripps).

Schmidt and his associates conclude from their experiments that the chemoreceptors do not play a rôle in the control of respiration under ordinary physiological conditions. This conclusion receives support from the observations of Cromer and Ivy

who found that dogs worked just as well on a treadmill after as before excision of the carotid bodies. Also, according to Dautrebande, a dog with its carotid and aortic chemoreceptors removed

and ultimate failure of the central neurons is the predominant effect of oxygen lack. The chemoreflex mechanism, on the other hand, according to Comroe and Schmidt, is highly resistant to

FIG. 159. Diagram to illustrate the nervous control of respiration.

FIG. 160. Effect of oxygen lack upon pulmonary ventilation in human subject. (After Means.)

carries out respiratory adjustments to high altitudes as well as a normal animal.

In more exacting emergencies, however, the reflex response of the chemoreceptors, especially to anoxia, is undoubtedly of the highest importance. Anoxia appears to be ineffective as a stimulus to the respiratory center. Depression

anoxia, retaining its viability and continuing to exert its influence upon the center which otherwise would be unresponsive in the body's emergency. These observers look upon the chemoreceptor mechanism as a more primitive type of respiratory control which serves as a last line of defense against respiratory failure—the *ultimum moriens* of the respiratory control system.

The chemoreceptors also appear to be relatively insensitive to the H ion. Such slight variations in hydrogen ion concentration of the blood as might occur under any condition of health could have little or no stimulating effect upon them. In experimental animals a relatively large shift in pH (namely 0.1) of the fluid perfusing the isolated carotid body is required in order to effect a change in respiration.

It should be mentioned in fairness to any discussion of the importance of the chemoreceptors in the control of normal breathing, that there is not universal agreement with the views just given. Records of the action currents in the sinus nerve show that impulses are discharged by the chemoreceptors in response to much smaller changes

in gas tensions of the arterial blood than those given above. It has been reported that a reduction in oxygen tension below 85 mm. Hg causes an increase in the activity recorded from the "chemical fibers" of the sinus nerve. Even during normal breathing, action currents can be recorded from the sinus nerve from which all but a few "chemical fibers" have been severed. There are two possibilities which throw some doubt on the validity of evidence derived from such studies, namely, that the impulses may not have their source in the chemoreceptors and that they may not affect the activity of the respiratory center even though they are of chemoreceptor origin. Still, the experiments of Watt, Dumke and Comroe who used respiratory activity as the index of chemoreceptor stimulation, provide evidence for tonic chemoreflex activity. They found that the inhalation of pure oxygen by unanesthetized dogs caused a reduction in breathing of as much as 31 per cent. This indicates that before the administration of oxygen the breathing had been under tonic chemoreflex control. The authors, concluded, nevertheless, that such control was not essential for normal breathing, because in some of their animals, the respirations, after an initial reduction, were restored to their original value although pure oxygen was being breathed. Watt and his associates support their belief in the absence of any significant influence, under ordinary conditions, upon the respiratory center through chemoreceptor mechanisms by the observation that no change in breathing follows denervation of the sinus.

REFLEXES INITIATED IN OTHER PARTS OF THE BODY

Stimulation of almost any afferent nerve may bring about a reflex change in respiration. Stimulation of pain fibers is especially potent in this regard and the respiratory effects of the excitation of the cutaneous nerves by extremes of heat or cold are well known. The great increase in pulmonary ventilation occurring in muscular exercise is to a large extent dependent upon reflexes originating in the active muscles. Proprioceptive impulses from the diaphragm and other respiratory muscles during one respiratory phase exert an important influence upon the succeeding movement.³ Stimulation of the abdominal viscera,

either during surgical operations or as a result of disease, may cause profound changes in breathing. The glossopharyngeal nerve contains afferent fibers which inhibit respiration during the second stage of the act of swallowing. Abrupt inhibition of respiration is also caused by the inhalation of an irritant gas through stimulation of nasal branches of the 5th nerve. In other instances irritation of these endings may cause sneezing—a modified respiratory act (see fig. 158). Coughing, though it can be brought about by a voluntary effort, is most commonly reflex in character, initiated by the stimulation of afferent nerve endings in the trachea and larynx (p. 303).

Important as is the rôle of CO₂ in stimulating respiration, even very high concentrations (9 per cent and higher) of the gas in the inspired air are not capable of inducing the greatest pulmonary ventilation possible. During strenuous muscular work the volume of air breathed by a vigorous man may amount to 120 liters per minute, whereas about 60 liters per minute is the maximum ventilation caused by the inhalation of high concentrations of CO₂. Yet in the latter instance the sense of effort (dyspnea) is, as pointed out by Barcroft and Margaria, much greater. The greater pulmonary ventilation caused by muscular exercise as compared with that resulting from the inhalation of CO₂ is due, it appears, to reflexes originating in the contracting muscles and possibly also to the irradiation of impulses from the motor cortex to the respiratory center (p. 348). Comroe and Schmidt have demonstrated the occurrence of pronounced hyperpnea (in both men and animals) upon passively exercising the limbs, which was abolished or very much reduced by section of the nerves but not by obstructing the circulation to the exercised limb.

The action of sensory impulses on the respiratory center is conditioned (1) by the afferent nervous impulses arriving at the center from other regions and (2) by the chemical environment of its cells. To illustrate (1) stimulation of the saphenous nerve in a dog causes acceleration of respiration with perhaps little change in amplitude. If the vagi are cut and the saphenous again stimulated there may be little effect on the rate but perhaps a definite change in amplitude (Gesell).

experiments suggest that a chemoreflex mechanism is present in this situation, but his results have so far not been confirmed by other workers. As Gesell has pointed out, the existence of such a chemoreceptor organ would explain the rapid breathing caused by multiple pulmonary emboli (p. 346) and by pulmonary edema.

³ Larsell has described specialized sensory endings in the lung tissue which possibly are chemoreceptor in function. The lung tissue would be an even more advantageous site for sampling the oxygen content of the blood than is the carotid or aortic arch. Pi Suner's

(2), inhibitory (vagal) and accelerator (saphenous) respiratory reflexes are reduced by a high CO_2 tension. During the period of low CO_2 tension of the blood following the injection of sodium carbonate (see below) stimulation of the saphenous nerve produces a greater increase in the respiratory rate than if the carbonate had not been injected (Gesell). Conversely, stimulation of the central ends of the vagus and saphenous nerves during the hyperpnea due to CO_2 excess causes less effect than does similar stimulation of these nerves during normal breathing.

CHEMICAL STIMULATION OF THE RESPIRATORY CENTER

The chemical control of respiration under ordinary physiological conditions is carried out through the action of carbon dioxide on the respiratory center. Haldane and Priestley found that in man a rise in the carbon dioxide of the alveolar air of only 0.2 per cent (equivalent to an increase of 1.5 mm. Hg pressure) was sufficient to *double* the pulmonary ventilation. It has already been pointed out (p. 346) that the chemoreceptors of the carotid and aortic bodies are relatively insensitive to the action of CO_2 .

Though there has been some difference of opinion on the subject, and some conflict between the experimental results of different investigators, it seems fairly well established that the effect of anoxia upon the center is mainly if not entirely one of depression rather than of excitation.

The manner in which carbon dioxide serves as a stimulus to the center has also been a subject of debate for a number of years. According to the view at one time, the activity of the center was regulated by the hydrogen ion concentration of the arterial blood, carbon dioxide serving as a stimulus simply because, in solution, it acted as an acid (H_2CO_3). Several facts, however, could not be reconciled with this idea. For example, sodium carbonate and sodium bicarbonate when injected into the blood stream in amounts which caused equal increases in blood pH had opposite effects upon respiration, the former salt reducing and the latter increasing pulmonary ventilation. Furthermore, carbon dioxide produced a much greater effect on respiration than did any other acid for a given pH change. The work of Jacobs threw light upon these apparently discrepant observations. He showed that, owing to the more ready penetration of carbon dioxide into cells, the intracellular H-ion concentration might be considerably higher than that of the surrounding fluid medium. When the petals of a certain blue flower (*Symphytum perigrinum*) which are pink

in an acid medium and blue in an alkaline one, were immersed in a solution of sodium bicarbonate (pH 7.4), they turned pink. Gessel, taking these observations into account, formulated a theory of respiratory control which dispelled much of the confusion surrounding the theory of the H-ion being the essential respiratory stimulus. He postulated that the determining factor was the hydrogen ion concentration *within the cells of the center itself*. The opposite effects of sodium carbonate and sodium bicarbonate upon the respirations were explained on the view, supported by experiment, that the carbonate lowers the CO_2 tension of the blood and thus leads to a greater flow of CO_2 from the tissues, whereas the carbon dioxide tension of the blood and tissues is increased by the bicarbonate. This conception seemed to establish the hydrogen ion concentration of the nerve cells as the paramount common factor in the chemical stimulation of the respiratory center, whether this was due to CO_2 , fixed acids, anoxia or reduced blood supply to the center. The latter two conditions, it was pointed out, would permit the accumulation of acid metabolites (which ordinarily are removed by oxidative processes) within the nervous tissue. Thus the center, stimulated by the acid products of its own metabolism, increased the pulmonary ventilation, in order, as it were, to satisfy its own oxygen requirements and so the needs of the body as a whole. It should be remembered, however, that at this time the chemoreceptors of the carotid and aortic bodies and their respiratory function were unknown. It appears now that the observed effects of anoxia upon respiration were due not to a direct action upon the center, but to reflexes initiated from these structures (p. 346). Nor is the hyperpnea caused by fixed acids due apparently to their direct effect upon the center, for the latter is less sensitive to a rise in H-ion concentration due to such acids than are the chemoreceptors. The hyperpnea of diabetic and other types of acidosis is probably of chemoreceptor origin.

To return to the question, "How does CO_2 act as a stimulus to the respiratory center?" Does it do so merely by raising the hydrogen ion concentration of the cells of the respiratory center, its greater power of penetrating cell boundaries rendering it more effective in this regard? There is reason to believe that CO_2 acts specifically upon the center, that is, in some way other than by raising the H-ion concentration. Krogh and his associates found, for example, that in human sub-

jects, though the hyperpnea caused by the inhalation of CO_2 was extreme, little change in arterial pH resulted. The ingestion of ammonium chloride, on the contrary, while producing a much more pronounced lowering of the pH of the arterial blood caused little or no increase in breathing. It would seem that the question of the greater penetrating power of carbon dioxide can be ignored in considering these results, for the experiments in which ammonium chloride was ingested were continued over a period more than long enough (up to 10 days) for the cells of the center to have come into equilibrium with the arterial blood. Bernthal points out, however, that though equilibrium may have become established between the concentrations of hydrogen ions in the arterial blood and in the respiratory center, there is reason to believe that there may not have been *equality* of concentrations and that, therefore, the arterial blood might not be a true indicator of the concentration of hydrogen ions within the cells. This problem of the action of carbon dioxide—whether due to some specific property as well as to its effect in raising the hydrogen ion concentration or to the latter effect alone has not been finally solved. It must be admitted that if it acts specifically, the manner in which it does so is unknown.

Any condition apparently which profoundly alters the relationship between their oxygen supply and the metabolic need at the time serves to stimulate the chemoreceptors. The immediate stimuli, it is thought, are the acid products of their own metabolism. Thus, not only anoxia but poisoning the cells with cyanide or sulphide, ischemia of the carotid body, or increasing its metabolism as by the application of heat, are all capable of eliciting a hyperpneic reflex. When, on the other hand, glycolysis is prevented by local poisoning with monoiodoacetic acid, which prevents the production of lactic acid, anoxia does not cause the usual respiratory response. The chemoreceptors, then, are seen as highly specialized cells capable, as it were, of sampling the blood for its oxygen content and, when necessary, of signalling a message to the respiratory center when the tissues generally are threatened with a dangerous degree of anoxia.

HYPERPNEA, FORCED BREATHING AND APNEA

Hyperpnea. An increase in the quantity of air breathed (minute volume) as a result of an in-

crease of either the rate or depth of respiration or of both, is called hyperpnea. Hyperpnea may be produced by impulses reaching the respiratory center from the cerebral cortex (as in excitement and other emotional states) or from the hypothalamus; by the stimulation of sensory nerves (e.g., pain, heat or cold applied to the skin, etc.), by conditions which increase the demand of the tissues for oxygen, e.g., muscular exercise, and by certain other factors to be mentioned in the section under dyspnea.

Apnea. If the lungs of an animal are over-ventilated for a minute or two, either by stimulating a sensory nerve and thus inducing reflex hyperpnea or by means of some mechanical respiratory device, a period follows during which all breathing is suspended. This period of respiratory arrest is called *apnea*. Apnea can also be induced by sending a stream of inhibitory impulses to the respiratory center, as by stimulating the central end of the vagus nerve or by distending the lungs and maintaining them in the inspiratory position, e.g., by clamping the trachea towards the end of inspiration. An apneic period can also be induced by the stimulation of the pressoreceptors in carotid sinus as may result from a sharp rise in blood pressure (p. 346) or by a direct chemical action upon the respiratory center, e.g., the injection of sodium carbonate into the blood stream or by the action of certain depressant drugs.

Any person can readily induce apnea in himself by overbreathing. When one breathes deeply and quickly for a few minutes and then stops he does not have any desire to breathe for the next minute or more. The deep and rapid breathing is termed *voluntary hyperpnea* or *forced respiration*.

The apnea following overventilation is due to the excessive elimination of carbon dioxide and in consequence to the lowering of the tension of this gas in the blood. Forced breathing in an atmosphere rich in carbon dioxide therefore does not cause apnea. Owing to the shape of the oxygen dissociation curve of hemoglobin, oxygenation of the arterial blood can be only slightly improved by forced breathing, and is therefore of little significance in the production of the apnea. Indeed, in the apneic periods of Cheyne-Stokes respiration there may actually be oxygen want sufficient in degree to cause pronounced cyanosis (Haldane and Poulton). Nevertheless, when forced breathing is carried out in an atmosphere rich in oxygen apnea may continue, in some instances, for as

long as 15 minutes (Schneider); the high percentage of oxygen in the inspired air causes a slight increase in the oxygen tension of the blood and in the tissues (Argyll Campbell).

Other effects of forced breathing

While the cardinal features of the reaction to forced breathing are now well known, there is considerable variety in detail when observed over a large number of cases. Variations seem due not alone to differences in rate and degree of the overventilation but to peculiarities which, for lack of a better understanding of them, may be termed constitutional and temperamental. In a class of over a hundred students two or three individuals may be found who can carry on forced breathing for ten minutes with comparatively little disturbance. On the whole these seem to be of rather robust physique, though not necessarily trained athletes.

Probably the first subjective observations of the student will be dizziness and faintness resulting in some relaxation of his efforts, but it is very rarely that a feeling of nausea becomes prominent.³ This initial discomfort may arise from a disturbance of the circulation directly due to the too vigorous movements of the chest, and for this reason instructions are given to assume the supine position and to force the depth rather than the rate of breathing. Within five minutes at the most, a regular rhythm has been established and the subject will have begun to notice numbness and tingling, probably coolness and perhaps tremors in various parts of the body and slight tightening of the muscles. In the majority of cases, samples of alveolar air taken at this time will show a level of carbon dioxide about one-half the normal, and only a slight further drop will occur as the experiment continues. The pulse and blood pressure will have risen, as would be expected with muscular exercise, but from now on signs and symptoms will begin to vary. The pulse and blood pressure may retain their relationship, or the pulse may rise without corresponding rise in pressure, but not infrequently the pulse rate increases while the pressure falls. It is usually in this last group of cases that one may find the cold clammy skin, pale cyanosis and thready pulse which form a curious anomaly. If enough hemoglobin is reduced to cause cyanosis it obviously is not holding its oxygen by reason of the alkalosis, and therefore the circulation must in some manner be restricted. The loss of carbon dioxide may interfere with the efficiency of the heart. There is evidence of vasoconstriction of the peripheral vessels, and vasodilatation of the vessels in the splanchnic area has been observed during surgical operations. Good evidence of circulatory disturbance exists in the coldness of the extremities. The condition is suggestive

of shock, and students who have experienced it may be impressed with the contrast to the flushed warm skin and pounding heart which occur when the breath is held to the breaking point (see also pp. 213 and 250).

Tetany varies from a slight stiffness of the muscles to well-marked contractures. In the hand the most common attitude is ulnar flexion with relative extension on the radial side and some flexion of the wrists. Before it is clearly evident it may occasionally be brought out by constricting the upper arm (Trousseau's sign). It would be expected on this account that tetany in the hands would appear first on the side upon which the blood pressure cuff has been applied, but in practice, this seldom occurs and occasionally even the reverse is true, suggesting that the interference with venous return incident to the blood pressure readings tends to delay the phenomenon. Tetany in the face can often be detected at a distance by a peculiar appearance of the eyes associated with a contraction of the surrounding muscles, particularly the inner part of the under lid. The involvement of deeper muscles can be brought out in the alterations of speech; occasionally the orbicular muscles of the mouth are considerably affected. A few subjects will note particularly contractions in the abdominal muscles and in the legs.

The hyperexcitability of the nervous system is almost always shown in the increased briskness of the knee jerk, but particularly in the facial nerve reflex elicited by tapping just below the zygoma (Chvostek's sign). On the whole this has proved one of the best early signs of the altered acid-base balance. The response can easily be distinguished from the reaction of an unexpected stimulus and from the vibration due to continuity of tissue. It makes its appearance as fine but definite contractions occurring around the eye, nose or corner of the mouth. Whereas in the knee jerk some comparison is made with the previous normal response, this is unnecessary in Chvostek's sign, so that the latter should be of more value in clinical examinations. Sometimes clonic spasms and shivering will persist through the greater part of an experiment.

It is after the first five minutes that certain temperamental differences may also appear. Whereas many, perhaps more cautious, keep themselves well in hand, coöperate easily in the taking of the samples and can stop the moment the signal is given, there are others, perhaps more adventurous, who develop symptoms more quickly, have a little difficulty in giving samples and finally have trouble in coming to a halt. Of the latter group some become somnolent and a few will appear amused and if set laughing have difficulty in controlling themselves. The condition has been described as one of mild intoxication, and in classes immediately after the war a student who had been an aviator remarked that his sensations resembled those resulting from a very rapid rise in altitude (see p. 361). The inability to stop promptly may be due in part to some

³ These observations on voluntary hyperpnea were kindly placed at our disposal by our colleague, Dr. Edward Fidler.

dulling of the special senses which is not appreciated by the student until during the apneic period he notes that sounds become closer and clearer. But this does not seem to be the sole reason of the difficulty, because occasionally, having been brought to a stop for a few seconds, the subject will break back into the previous rhythm. This condition suggests a loss of control of the upper over the lower neuron, a marked contrast to the state of affairs at the beginning of the experiment. It also resembles a fixation of ideas. If cyanosis be present, the inference can be made that the stagnant type of anoxia (p. 359) can occur with forced breathing—an apparent paradox.

The apneic period is variable in length depending on the degree of disturbance and is, of course, prolonged if oxygen is taken during the last few breaths of the forced breathing. Whether cyanosis has appeared before or not it is almost certain to be present with an apnea of more than thirty seconds. During long periods the change may be very striking where the texture and color of the skin enhance the contrast.

the famous London surgeon of the 18th century.) In this type of breathing the respirations may be described as alternately waxing and waning. That is, a period of breathing occurs in which the individual respirations are small and slow to start with but gradually increase in depth and rate to a maximum and then, subsiding again, finally cease for a time (fig. 161). The hyperpneic and apneic phases last each for about 30 seconds. Periodic breathing of this type occurs at high altitudes and is exhibited by such animals as the ground hog and the dormouse during hibernation. A tendency to this type of breathing is not uncommonly shown by healthy infants and occasionally by normal adults during sleep. The most common clinical conditions in which Cheyne-Stokes breathing occurs are advanced renal and cardiac disease, asthma and raised intracranial pressure. It is also seen in severe pneumonia and in morphine

FIG. 161. Two examples of Cheyne-Stokes breathing. (After Lewis.)

The return of breathing occurs more frequently with a single breath, usually rather small, followed by a secondary apnea. Succeeding movements gain in extent while apneic periods decline until normal breathing is reached. Typical Cheyne-Stokes breathing, which at one time was considered a common characteristic, has been quite rare. In several hundred experiments carried on by students during the past fifteen years only one striking case has appeared in which the phenomenon continued over a space of four or five minutes.

The decrease in acidity of the urine has been demonstrable in most of the tests but disappointing results occasionally occur where the acidity is low before the experiment and the forced breathing is of mild character.

PERIODIC RESPIRATION

Periodic breathing is the term applied to various types of uneven respiratory rhythm. The most common type is called Cheyne-Stokes breathing after two physicians who described it. (It had been described earlier, however, by John Hunter,

and chloral poisoning, or it may follow a general anesthetic. As mentioned above, it occurs, though rarely, after a bout of forced breathing. Douglas and Haldane induced it in normal persons by a moderate degree of oxygen want. Clinical Cheyne-Stokes respiration is usually a grave omen and is probably the result, in most instances at any rate, of damage to the respiratory center caused by oxygen lack. The latter may be the result of defective aeration of the blood in the lungs or of slowing of the circulation through the medulla (e.g., circulatory failure or raised intracranial pressure). The periodic rhythm is abolished in many cases by oxygen administration. It is apparently developed in the following way. The depressed state of the respiratory center results in weak shallow respirations which intensify the anoxia. The oxygen lack stimulates the respirations and, according to Douglas and Haldane, also increases the sensitivity of the center to CO_2 . The respirations increase in vigor but subside as the CO_2 is eliminated. The period of

breathing, however, has reduced the CO_2 tension of the blood below the level at which the center is stimulated; apnea ensues. The apneic period, of course, increases the anoxia and prevents the elimination of CO_2 ; the center is stimulated directly, as well as through a chemoreceptor reflex and the breathing returns, but ceases again when, through the absorption of oxygen and the blowing off of CO_2 , the center is no longer excited. It has also been pointed out by Douglas and Haldane that the elimination of large quantities of CO_2 from the body during the hyperpneic periods and the ultimate reduction of the bicarbonate reserve removes a steadying influence which is normally exerted upon the respiratory center. (They compare this effect to that of the fly-wheel of a motor.) The body normally holds a large store of CO_2 in the lungs and tissue fluids (as bicarbonate) which is drawn upon to oppose any sudden fall in CO_2 tension of the blood supplying the respiratory center. Any sharp increase in CO_2 tension, on the other hand, is prevented through the excess CO_2 being buffered by the tissue fluids. In Cheyne-Stokes breathing the reduction of the bicarbonate reserves permits slight changes in the gas tensions to produce sudden and exaggerated fluctuations in the activity of the center. CO_2 administration as shown by Allen and Pembry abolishes in many instances the periodic rhythm.

A manner in which periodic breathing might possibly be produced in cases of raised intracranial pressure is suggested by an experiment of Eyster. He increased the intracranial pressure in dogs and found that when the arterial blood pressure rose and fell alternately above and below the intracranial pressure, Cheyne-Stokes breathing ensued. In clinical cases of raised intracranial pressure similar alternating elevations and depressions of the blood pressure have been observed by Eyster, the hyperpneic phase coinciding with the blood pressure rise. The blood pressure changes may be the immediate cause of the respiratory rhythm in these cases. It is easy to conceive that a fall in arterial pressure below intracranial pressure by causing acute anemia of the center would suppress its activity for the time and induce apnea; this would give place to hyperpnea during the phase of raised arterial pressure when blood again filled the vessels of the center.

A type of respiratory periodicity known as Biot's breathing is seen in disease, e.g., meningitis, involving the region of the medulla. This differs from the Cheyne-Stokes type in that the onsets of the apneic and hyperpneic phases are abrupt. The two phases are frequently also unequally spaced.

DYSPNEA

Definition

Dyspnea means literally difficult breathing. When the respirations from whatever cause cannot be carried out with ease and practically unconsciously the individual is said to be dyspneic. The term therefore generally implies a subjective element. Dyspnea thus differs from hyperpnea. The latter term means simply increased pulmonary ventilation, and this may occur quite unconsciously or if the subject is aware of the augmentation of the breathing there is not necessarily any sensation of difficulty or distress. When the hyperpnea becomes extreme and yet leaves the need for which it had been instituted unsatisfied, discomfort or distress is experienced and the term dyspnea is applicable. Meakins offers the following concise definition; "dyspnea is the consciousness of the necessity for increased respiratory effort."

THE CAUSES OF DYSPNEA

Since the respiratory and circulatory functions are directed toward the acquisition of oxygen and the elimination of carbon dioxide, dyspnea may result if either of these functions be disturbed to such an extent that the normal gaseous exchanges cannot be accomplished. On the other hand the oxygen requirement and the carbon dioxide production may be so great that the *normal* respiratory and circulatory mechanisms find difficulty in meeting the demands of the moment. Or again the supply of oxygen itself may be inadequate as a result of a low oxygen tension in the atmosphere (e.g., high altitudes). In considering the causes of dyspnea we must therefore in many instances look beyond the lungs themselves. The lungs are the bellows but it is of course the tissues which consume oxygen and produce carbon dioxide; and it is the heart and the blood which are concerned with the carriage of these gases between lungs and tissues. As already mentioned dyspnea is the sensation of respiratory distress. The height of the hyperpnea at which dyspnea appears is called the *dyspneic point*. There is a relationship between the latter and the *vital capacity*. A person with a large vital capacity obviously can breathe a larger volume of air without discomfort than can one with a smaller vital capacity. There is a closer relationship however between the onset of dyspnea and the ratio of the *functional residual air* (that is, the quantity of air in the lungs at the end of

an ordinary expiration) to the *total lung capacity*, (i.e. the total volume of air which the lungs can hold during full inspiration (p. 308)). In health the ratio is about 2 to 5. The more nearly equal are the volumes of the functional residual air and the total lung capacity, the greater will be the tendency to dyspnea.

The fundamental or immediate causes of dyspnea can in most instances be reduced to the following categories. (1) Stimulation of the respiratory center either (a) reflexly from the carotid and aortic bodies (anoxia or increase in H-ion concentration due to fixed acids), (b) directly, by CO₂ excess, (c) a combination of (a) and (b) as in asphyxial states, or (d) by impulses from cerebral centers or by afferent impulses, especially of a painful character, from abdominal or peripheral regions. (2) Hypersensitivity of the Hering-Breuer reflex, thus bringing about earlier inhibition of the inspiratory phase and causing as a consequence a more rapid shallow type of breathing.

The chief abnormal conditions associated with dyspnea are:

(1) Prevention of adequate oxygenation of the blood in the lungs. That is, anoxia of the anoxic type (p. 358). This may result from (a) pulmonary disease or from laryngeal or tracheal obstruction, or (b) low O₂ tension in the inspired air, e.g., high altitudes.

(2) Interference with the transport of the respiratory gases (a) circulatory failure, (b) anemia—anoxia of the stagnant and anemic types respectively.

(3) Restriction of the action of the diaphragm or intercostals.

(4) *Acidosis*, reduced alkali reserve or retention of CO₂ (gaseous acidosis).

(5) Increased metabolism.

(6) *Nervous conditions*, e.g., emotional disturbance, neurasthenia, hysteria, encephalitis, or the direct stimulation of the respiratory center by cerebral tumor, hemorrhage or edema.

Dyspnea due to pulmonary diseases

Dyspnea is a feature of various respiratory diseases.

(a) In some instances, e.g., laryngeal or bronchial obstruction and asthma, the dyspnea is due to a combination of anoxia and CO₂ retention.

(b) In other instances owing to the reduced distensibility of the lungs resulting from edema, congestion, inflammation, fibrosis, etc., the Hering-Breuer reflex is abnormally sensitive.

(c) Limitation of the movements of the diaphragm and chest wall. In emphysema, for example, owing to the loss of lung elasticity the resting position of the chest is one of nearly full inspiration. The diaphragm is fixed and the thorax elevated. Any further enlargement of the chest entails unusual effort on the part of the intercostal muscles (see also p. 368) and the enlistment of the accessory muscles of respiration. Expiration involves active contraction of the expiratory muscles.

Cardiac dyspnea

Dyspnea upon exertion is a feature of certain chronic heart lesions, e.g., mitral stenosis. Stimulation of the carotid and aortic bodies by oxygen want or of the respiratory center by carbon dioxide excess is not *in the absence of cardiac failure*, responsible for the dyspnea, since the oxygen saturation of the arterial blood is not reduced to any important degree and the carbon dioxide tension is within or even below the normal range. Pulmonary engorgement leading to diminished distensibility of the lung is considered by Meakins, Christie and associates to be the prime cause of cardiac dyspnea. Though the reduction in the vital capacity may be roughly proportional to the dyspnea, the two do not bear the relationship of cause and effect, since the subject's vital capacity is always greater than the volume of air required for the exertion which causes the dyspnea. Owing, however, to the diminished distensibility—the stiffness of the lung—a greater inspiratory effort is expended in breathing the extra volume of air which the muscular exertion demands. The lung might be compared to stiffened bellows leather; more force is required to distend it. The elasticity of the lung is also moderately reduced so that expiration instead of being a passive act brought about largely by the recoil of the lung now requires the aid of the contraction of expiratory muscles in order to “squeeze” the air from the chest. The intrapleural pressure, therefore, instead of remaining “negative” throughout the respiratory cycle becomes positive toward the end of expiration (Christie and Meakins). The decreased distensibility of the lung, for the same reason that it increases the difficulty of enlarging the volume of tidal air, reduces the vital capacity. In other words the dyspnea and reduced vital capacity are due to a common cause. The reduced distensibility will also have the effect as already mentioned, of increasing the sensitivity

of the Hering-Breuer reflex with the production of shallow breathing.⁴

In *congestive heart failure* with marked slowing of the circulation there is commonly hyperpnea and dyspnea even during rest and then there may be added to the pulmonary factor itself the stimulating effect of carbon dioxide excess upon the respiratory center but, according to Christie and Meakins, this is of minor importance. When pulmonary edema supervenes, interference with the absorption of oxygen and the production of arterial anoxemia (stimulation of carotid body) may possibly be a factor. Hindrance to the absorption of oxygen, caused by the presence of exudate in the alveoli and the edematous swelling of the alveolar walls, is accompanied by little or no interference with the elimination of carbon dioxide; this is probably due in part to the much greater solubility of carbon dioxide than of oxygen and, in consequence, to the freer diffusion of the former gas through the edema fluid. Nevertheless, in congestive heart failure arterial anoxemia with a normal or even a subnormal carbon dioxide content of the arterial blood may exist even in the absence of pulmonary edema. Unequal ventilation of the alveoli—underventilation of some and over-ventilation of others—is probably the principal cause of the anoxia (chapter XXXV) in these instances (p. 365). Diminished distensibility and elasticity of the lung would tend to favor the ventilation of peripheral alveoli at the expense of those placed more centrally. In other words, the normal tendency towards unequal ventilation of the alveoli is exaggerated by diminished distensibility of the lung tissue.

Experimental support can be cited for the view that reduced distensibility of the lungs as a result of congestion is an important factor in cardiac dyspnea. Harrison and his associates have shown that increased pressure in the pulmonary capillaries causes rapid, shallow breathing which is abolished by vagal section. The production of multiple emboli in the pulmonary capillaries by the intravenous injection of starch granules causes congestion of the lungs and rapid shallow breathing (p. 366) and Partridge has shown that after rapid breathing has been induced in this way the impulses recorded from the vagus nerve are of higher frequency than those resulting from inflation to an equal degree of normal lung. It has also been shown that in man pulmonary conges-

tion does actually reduce the distensibility of the lung tissue.

Harrison and his colleagues found in subjects of cardiac failure the CO_2 content of the jugular blood to be within normal limits and observed no significant reduction in the cerebral blood flow (i.e., through the respiratory center). They suggest that afferent impulses initiated from the great veins at the base of the heart as a result of the high venous pressure, as well as impulses from the congested lungs, excite the respiratory center.

Though there is much to be said for the reflex origin of cardiac dyspnea, not all are agreed as to its paramount importance. McMichael, for example, in a clinical study found a reduction in cardiac output in those subjects showing hyperpnea (which is always associated with the dyspnea) during rest. The hyperpnea showed a closer correlation with the cardiac output than with the vital capacity which, he points out, is contrary to what might be expected were congestion of the lungs the dominant causative factor. He is inclined to believe that the hyperpnea and dyspnea of the cardiac patient *during rest* is due to reduced blood flow through the center (i.e., chemical stimulation).

ORTHOPNEA. In congestive heart failure with dyspnea at rest the breathlessness is usually more pronounced in the recumbent than in the sitting position. When propped up with pillows the patient may be quite comfortable but becomes dyspneic when he lies down. Many theories have been advanced in attempts to explain the less difficult breathing in the upright position. Among these are:

(a) Removal of the weight of the abdominal viscera which interferes with the descent of the diaphragm in the recumbent position.

(b) Better draining of blood from the medulla and in consequence, augmentation of the flow through the respiratory center.

(c) Draining of blood from the chest and the relief of pulmonary congestion. This is probably the most important factor. The distensibility of the lung is thereby increased and the Hering-Breuer reflex rendered less sensitive. The vital capacity is less in the recumbent than in the sitting posture. This is true even for the normal person but in cardiac cases the effect is accentuated by the vascular engorgement and decreased distensibility of the lung induced by recumbency. Nevertheless, as already mentioned, reduction in the vital capacity is not itself responsible for the dyspnea.

⁴ The beneficial effects of morphine upon cardiac dyspnea are very probably brought about through the reduction in the sensitivity of the vagal endings.

CARDIAC ASTHMA. This is the term applied to paroxysmal attacks of dyspnea occurring, usually at night, in subjects of heart disease associated with hypertension and advanced arteriosclerosis. The upright position tends to relieve the dyspnea. The cause of the attack is unknown, though Christie and Meakins suggest that it is due to pulmonary congestion and a sudden decrease in pulmonary distensibility. During the attack, according to Weiss and Robb, there is engorgement of the pulmonary vascular bed, a tendency to pulmonary edema and a marked reduction in the oxygen saturation of the arterial blood.

Dyspnea in anemia

When at rest, the anemic subject is as a rule not dyspneic. The hemoglobin though reduced in amount becomes fully saturated with oxygen in the lungs. The oxygen tension and consequently the quantity of the gas in simple solution in the arterial blood are normal. The arterial blood of a patient whose hemoglobin is 30 per cent of the normal value will, however, contain only a little over 6 volumes per cent of oxygen. In the healthy resting body the blood in its passage through the capillaries gives up at least 5 volumes per cent. If the velocity of blood flow through the tissues in anemia were the same as during health a unit volume of blood would give up an equivalent amount of oxygen. This would leave a reserve of only 1 volume per cent, i.e., the venous blood would be almost completely reduced. The great proportion of the oxygen load of the blood would be supplied to the tissues at a very low pressure (see dissociation curve, p. 320) and anoxemia would result. The circulation rate (cardiac output) is, however, increased in anemia so that each unit of blood gives up a smaller part of its oxygen load. The oxygen is therefore delivered to the tissues at a higher pressure than would otherwise be possible. For this reason the patient is not dyspneic while resting even though his hemoglobin is greatly reduced.⁵ Not only is the output of the heart increased but a redistribution of the blood occurs. The vessels of the skin are constricted and a greater proportion of the total blood volume is driven through other regions. The extent to which the circulatory readjustments can compensate for the blood defect is limited, therefore during exertion the extra demand for oxygen cannot be met.

⁵ Fahr and Ronzone reported a case in which the hemoglobin was 12 per cent of the normal and the arterial blood contained only 2.2 volumes per cent of oxygen. There was no dyspnea during rest.

Oxygen want follows, the respiratory mechanism (carotid body) is stimulated; hyperpnea and dyspnea result.

It is to be remembered that in anemia the carriage of carbon dioxide may also be interfered with since hemoglobin constitutes an essential part of the mechanism provided for the transport of this gas (see chapter XXXIII).

Dyspnea due to increased metabolism

IN HEALTH, muscular exercise is the outstanding cause of a great increase of metabolism. Carbon dioxide is produced in excessive amounts both from oxidative processes and by the interaction of lactic acid with bicarbonate and acts as a powerful stimulus to the respiratory center. The increased pulmonary ventilation in exercise is due in part only to stimulation of the center by CO_2 . Reflexes initiated in the active muscles and the irradiation of impulses from the motor cortex also play an important part (p. 349). As the severity of the exercise is increased, hyperpnea merges into dyspnea. The athlete and the untrained person differ widely in respect to the degree of muscular exertion which will produce this physiological type of dyspnea. The difference depends upon the following factors:

(a) *Vital capacity.* In the average normal man the pulmonary ventilation increases from 4 to 5 fold before the dyspneic point is reached. The athlete on the other hand, since his vital capacity is greater shows a correspondingly greater increase in his pulmonary ventilation before dyspnea supervenes. The existence of any pulmonary condition which reduces the vital capacity will depress the level of the dyspneic point.

(b) *Circulation rate.* The trained man can increase his circulation rate to a greater degree than the untrained and so deliver more oxygen to his tissues at high pressure.

(c) *Neuromuscular integration.* Co-ordination of the several muscles in a given muscular act is more precise in the trained than in the untrained man. There is thus less waste of effort. In the performance of a given amount of work, therefore, the untrained man consumes a greater volume of oxygen, i.e., he is a less efficient machine. Yet his respiratory center appears to be more sensitive to nervous influences—impulses from the contracting muscles and from the cerebral cortex.

A PATHOLOGICAL INCREASE IN METABOLISM, e.g., hyperthyroidism, fever, etc., cannot apparently in the absence of some respiratory or circulatory abnormality cause dyspnea during rest. The increase in metabolism would need to be

around 300 per cent before dyspnea might be expected to occur and such a metabolic level is never reached in these or any other pathological condition. Nevertheless, in hyperthyroidism dyspnea will follow upon a degree of exertion which would cause no distress in a healthy person, for the greater metabolic rate, due to the disease, added to that of the exercise will increase the metabolism sufficiently to raise the pulmonary ventilation above the dyspneic point. The dyspnea of hyperthyroidism, when pulmonary and cardiovascular complications are absent is therefore like that of anemia, evident only upon exertion. In hyperthyroidism there is also a reduced vital capacity (which will lower the dyspneic point) as well as a diminution of muscular efficiency.

Dyspnea due to acidosis

The importance of the part played by pulmonary ventilation in resisting a rise in the hydrogen ion concentration of the body fluids has been dealt with elsewhere (p. 107). Little more need be said here. Non-volatile acids, e.g., lactic in muscular exercise, β -hydroxybutyric and acetoacetic acids in diabetes, and retained acids in nephritis, react with bicarbonate. The alkali reserve becomes reduced, but the ratio,

$$\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3} = \frac{1}{20}$$

is maintained through the stimulating effect of CO_2 upon the respiratory center. It is thus that the CO_2 tension of the alveolar air (and so of the

arterial blood) is kept at a level proportional to the reduction in the denominator of the equation. When this can no longer be effected, i.e., when the hydrogen ion concentration of the blood rises, the acidosis being then uncompensated, the center is stimulated mainly through reflexes initiated from chemoreceptors of the carotid and aortic bodies.

J. B. S. Haldane produced a severe acidosis and dyspnea in himself by the ingestion of acid forming salts (CaCl_2 and NH_4Cl). But as a matter of fact, the production of fixed acids in diseased conditions rarely causes such a high degree of hyperpnea that dyspnea results, unless the circulatory and respiratory mechanisms are very inefficient or the metabolic rate is increased. According to Means the "alkali reserve" must drop to around 12 volumes per cent before dyspnea supervenes as a result of the acidosis itself. In milder grades of acidosis, however, dyspnea, as in hyperthyroidism occurs upon exertion. The hyperpnea due to the increased metabolism of the exercise is then added to that due to the acidosis, with the result that the dyspneic point is soon reached.

Carbon dioxide retention may, as in emphysema, be accompanied by a compensatory rise in bicarbonate and a normal blood reaction (compensated CO_2 excess); dyspnea is not a notable feature in this condition. In other instances of CO_2 retention compensation is incomplete (uncompensated CO_2 excess or gaseous acidosis) and dyspnea results. In others, again, the CO_2 retention is due to the depression of the respiratory center itself, as in morphine narcosis; in such instances, though compensation is incomplete, dyspnea of course does not occur.

CHAPTER XXXV

ANOXIA

CLASSIFICATION AND DEFINITIONS

The failure of the tissues, for any reason, to receive an adequate supply of oxygen is called *anoxia*, *hypoxia*, *oxygen lack* or *oxygen want*. Anoxia may result from (a) defective oxygenation of the blood in the lungs, (b) lowered oxygen capacity of the blood, or (c) slowing of the movement of blood through the capillaries. Upon the basis of these three causes, oxygen want has been classified by Barcroft into *anoxic*, *anemic* and *stagnant* types, respectively. A fourth type, the *histotoxic* (Gk. *histos*, tissue, and *toxikon*, poison), caused by poisoning of the oxidative processes of the tissues has been added by Peters and Van Slyke. *Anoxemia* is a term which denotes a low tension of oxygen in the arterial blood, and is used synonymously with anoxic anoxia. *Asphyxia* is sometimes used interchangeably with anoxia, but, strictly speaking, this term should be restricted to conditions in which there is anoxia combined with an increased tension of carbon dioxide in the blood and tissues.

THE ANOXIC TYPE OF ANOXIA [HYPOXIA]

Normally, as we have seen, the blood leaves the lungs only about 95 per cent saturated with oxygen. When it reaches the tissues it contains, therefore, about 19 volumes per cent of oxygen when normal oxygen capacity is 20 vols. per cent. Oxygen is consequently at high pressure in the plasma. During rest only 5 volumes or so per cent of the gas are abstracted, i.e., the mixed venous blood coming to the lungs contains about 14 volumes per cent (around 70 per cent saturated). As will be seen from the dissociation curve of oxyhemoglobin the supply of this quantity of oxygen is associated with a drop in oxygen pressure to only 40 mm. Hg or so. A high pressure gradient from capillary to tissue cells is therefore assured. In the anoxic type of anoxia the saturation of the arterial blood and the oxygen partial pressure are reduced. When the saturation is, say, 50 per cent, there are still 10 volumes per cent of oxygen in the blood available for the tissues. Since the latter require only 5 volumes, 10 volumes apparently should be adequate. But this load is held at a relatively low pressure, about 25 mm. Hg. In order then for the blood in the capillaries to supply the necessary 5 volumes per cent, i.e., in order for the oxy-

gen saturation to be reduced to only 25 per cent, the pressure must fall to around 15 mm. Hg. The oxygen obviously must be delivered at a very low pressure head even were the pressure at zero within the tissue cells. It has already been pointed out that the intracellular pressure is considerably above zero and that, in the case of muscle at least, a lowering of the oxygen tension in the blood, the blood-flow remaining constant, cuts down the oxygen consumption of the tissues.

The chief clinical manifestations of the anoxic type are; dyspnea (p. 353), cyanosis (p. 372), mental disturbances, e.g., exhilaration, delirium, mania or fixed ideas. The intensity of the effects upon the body of a low oxygen tension in the arterial blood is influenced by (a) the abruptness of the onset of the anoxemia, (b) its degree, (c) its duration and (d) the general physical condition of the body.

The anoxic type of anoxia is produced by the following conditions:

- (1) Low oxygen tension in the inspired air:
 - (a) Vitiating of the atmosphere by inert gases.
 - (b) High altitudes, mountain sickness.
- (2) Abnormalities of the pulmonary mechanisms, pneumonia, asthma, emphysema, collapse of the lung, pulmonary edema or water in the lungs of the nearly drowned, obstruction of the air passages and paralysis of respiration.
- (3) Direct communication between the right and left sides of the heart through which venous blood is short circuited—shunt.

THE ANEMIC TYPE

The anemic type is caused by (a) *hemorrhage* or *anemia* from whatever cause, (b) *carbon monoxide poisoning* (p. 372), (c) *poisoning by nitrites and chlorates* which like carbon monoxide form stable compounds with hemoglobin (p. 46). In the anemic form of anoxia (resulting from anemia) (a) the total load of oxygen is reduced in proportion to the reduction in the hemoglobin. The oxygen tension and consequently the amount of the gas in simple solution is, however, the same as in health and the hemoglobin present in the arterial blood is 95 per cent saturated. In other words what hemoglobin there is, holds its full oxygen

load. Yet a great fall in oxygen pressure must occur in the capillary blood in order that the tissues shall receive their quota of oxygen, for, since there are fewer red cells each must give up a larger part of its load than normally. As a consequence, therefore, unless the rate of blood flow increases a large part of the oxygen supply must be delivered at low pressure (see also p. 356).

THE STAGNANT TYPE

In the anoxia due to a slowed circulation, the saturation of the arterial blood, its total oxygen load and its oxygen tension are all normal. A large part of the oxygen supply is, however,

blood flow, the blood of an arm vein having the oxygen saturation of arterial blood.

THE HISTOTOXIC TYPE

In this type, as its name implies, the respiratory mechanisms of the tissues are poisoned. The cells are unable to use the oxygen carried to them and, as a result, the capillary and venous bloods contain more oxygen and has a higher oxygen tension than normally (see Cyanide poisoning, p. 372).

The four types of anoxia are represented in figure 162. It will be noted that in the anoxic type only, is the arterial saturation low. In the

FIG. 162. Diagram illustrating types of anoxia. Columns representing arterial blood (A) and venous blood (V) are superimposed upon the oxygen dissociation curve. The black portion of the column represents reduced hemoglobin and the shaded portion, oxygenated hemoglobin. In the case of anemic anoxia the dotted portion of the columns represents hemoglobin that is either lost, as in true anemia, or unfit for oxygen transport, as in carbon monoxide poisoning. The perpendicular arrows denote the volume of oxygen given up to the tissues from a unit of blood. (After Means, with additions.)

delivered under low pressure, since each portion of blood gives up a larger proportion of its load owing to the slower blood flow, and its longer stay in the capillaries. Slowing of the circulation from whatever cause will induce the stagnant type of anoxia. It therefore occurs in the following conditions: (a) *heart failure*, (b) *obstruction of the venous return from a part (local anoxia)*, and (c) *surgical shock*. Pronounced slowing of the peripheral blood flow can be readily induced in a normal person by the application of cold. Meakins and Davies found that the venous blood of an arm vein was completely reduced after the hands had been kept in cold water for a time. Hot water, on the other hand, speeded up the peripheral

first two types the saturation of the hemoglobin in the venous blood is subnormal. In the anemic type, the hemoglobin, although reduced in amount, is nearly fully saturated, as in health. In the histotoxic type, as a result of the action of the poison upon the oxidative processes of the tissues (p. 372) the oxygen saturation of the venous blood approaches that of arterial blood.

CONDITIONS ASSOCIATED WITH THE ANOXIC TYPE OF ANOXIA

LOW OXYGEN TENSION OF THE INSPIRED AIR

Vitiation of the Atmosphere by Inert Gases

The atmosphere may have a low oxygen tension yet the barometric pressure be no lower than

usual. That is, other gases are present which displace the oxygen and so reduce its percentage in the atmosphere. In mines for example the air may contain "Fire Damp" (methane) or "Black Damp" (nitrogen, CO_2) which lower the percentage of oxygen in the air though the barometric pressure is actually higher than that at sea level. These gases, under such circumstances produce no direct deleterious effect upon the body. They act simply by reducing the oxygen tension of the atmosphere. They therefore differ in this respect from carbon monoxide (p. 371), which when occurring in mines in dangerous concentrations is spoken of as "after damp."

Mountain sickness

At high altitudes the percentage of oxygen in the atmosphere is the same as at sea-level but the barometric pressure is low and the partial pressure of oxygen is reduced to a corresponding degree. If the barometer, for example, registers a pressure of 600 mm. Hg the oxygen pressure is $\left(\frac{20.96}{100} \times 600 =\right)$ 125.76 mm. Hg. Mountain sickness as first shown by Paul Bert is due to the low partial pressure of oxygen in the atmosphere and to the resulting anoxemia, not to the low barometric pressure itself. The effects resulting from breathing atmospheres low in oxygen but possessing a high total pressure are in many respects similar to those of mountain sickness. On the other hand if an animal be placed in a steel chamber and the barometric pressure lowered to $\frac{1}{4}$ or $\frac{1}{2}$ of an atmosphere no ill effects result, provided the air is enriched with oxygen, i.e., if its percentage be raised to maintain its partial pressure at the normal figure.

The first signs and symptoms of oxygen want usually make their appearance in healthy unacclimatized persons when they ascend to an altitude of 10,000 feet or more above sea-level. The height at which mountain sickness appears varies considerably, however, in different individuals depending upon their fitness, the rapidity with which the ascent is made and upon the degree of muscular effort undertaken. From 23,000 to 25,000 feet is around the limit to which unacclimatized men can ascend without the aid of an artificial oxygen supply. Though in the attempt to scale Mount Everest's peak in 1924 a height of

around 29,000 feet was reached. The two of the party of this expedition, George Mallory and Andrew Irving, who ascended to the greatest height lost their lives. Their bodies were not recovered and it is not known whether they died as a result of oxygen want, exposure or by falling. In 1875 the three French scientists, Crocé-Spinelli, Simon and Tissandier ascended in a balloon. A height of over 26,000 feet (Bar. 270 mm. Hg) was reached. Consciousness was lost at about 25,000 feet. When Tissandier regained consciousness the balloon was falling rapidly, but his two companions were dead. Oxygen containers were carried in the ascent but Tissandier records that his arms became powerless and so he was unable to raise the mouthpiece to his lips. In 1901 Berson and Simon made a balloon ascent with the aid of oxygen to 36,000 feet. In recent years aeroplane and balloon ascents to much higher altitudes have been made (72,395 feet by Stevens and Anderson in 1935). Aeroplane ascents above 12,000-13,000 feet without oxygen are risky.

Several mountain climbing expeditions have been made in the past by different groups of physiologists for the purpose of studying the effects of low oxygen tensions upon the respiratory functions and of determining the factors underlying the phenomenon of acclimatization. An expedition was made to Mont Rosa (15,000 feet) in 1894 by Mosso and by others subsequently; to the peak of Teneriffe (12,000 feet) in 1910 by Zuntz, Barcroft and associates, and in 1912 to Pike's Peak (14,100 feet) by the Anglo-American expedition of which Haldane, Douglas, Henderson and Schneider were members. In 1921-1922 Barcroft headed a party to Cerro de Pasco (14,200 feet) in the Peruvian Andes. A Himalayan expedition was led by Hartman in 1931, and in 1935 Dill led a party to the Chilean Andes.

It may be useful to the reader to remind him of certain fundamental physical principles involved in ascents to high altitudes before considering the physiological effects. As the pressure becomes reduced with increasing altitude the gases of the atmosphere and in the lungs must, of course, expand. It follows that the quantity of oxygen and other gases of the atmosphere per unit volume becomes reduced proportionately. For this reason at great altitudes (above 28,000 feet) the inhalation from a cylinder of even pure oxygen will not

prevent anoxia.¹ The pressure of oxygen in the lungs of a person breathing pure oxygen at a height of say 40,000 feet would be only about 60 mm. Hg and his arterial blood only 88 per cent saturated with oxygen. A closed cabin containing air at a higher pressure (equivalent to an altitude of around 8,000 feet) is the only way in which the problem of anoxia in high altitude flying can be solved satisfactorily. Even then there is the danger of leaks, especially in military flying from enemy action. Were the airmen thus suddenly exposed to the low pressure existing at altitudes above 35,000 feet, acute anoxia would result, consciousness being lost within a few seconds.

GENERAL SIGNS AND SYMPTOMS. Aeroplane ascents, if made rapidly without the use of oxygen, may result in sudden loss of consciousness due to the reduction in oxygen supply to the brain. When the ascent is made more slowly, or the altitude is not so great as to cause immediate loss of consciousness, the aviator may at first experience sensations of excitement, exhilaration and well-being. As higher altitudes are reached effects of a more serious nature develop, often insidiously. Mental and sensory dullness, muscular weakness, headache, vomiting, cyanosis, dyspnea and perhaps a tendency toward periodic breathing may be induced. A common and dangerous effect is the development of fixed ideas which may result in the performance of foolhardy and ill-judged actions.

When a person climbs to a mountain height the time taken in the journey allows a certain degree of physiological readjustment to take place and the symptoms are usually less intense. But, in the case of the aviator, mental features, e.g., feeling of elation, exhilaration, talkativeness and sometimes emotional outbursts, laughing or crying, quarrelsomeness or the development of fixed ideas, are prominent. Mental tasks, e.g., calculations, memory tests, and telling the time from

A rough calculation will make this clear. At 40,000 feet the atmospheric pressure is about 141 mm. Hg, i.e., less than $\frac{1}{3}$ the pressure at sea level. A unit volume of air, therefore, contains less than $\frac{1}{3}$ as much oxygen as the same volume at 760 mm. Hg pressure. A given volume of pure oxygen would contain less than the number of oxygen molecules at 40,000 feet as would at sea level. That is to say, a given space at former level could not contain as much oxygen as a corresponding volume of air would contain at the pressure of 1 atmosphere. Making allowance for the pressure of water vapor (47 mm.) and CO₂ (36 mm.) the partial pressure of oxygen in the lungs at 40,000 feet if pure oxygen was being breathed would be only $-(47 + 36) = 58$ mm. Hg.

the mirror image of a clock face are performed less efficiently. Similar effects upon the mind are produced upon persons exposed to low oxygen pressures within a steel cabinet. The mental effects as pointed out by Barcroft are not unlike those caused by drunkenness. To quote his words,

"Alcohol affects different persons in different ways: so on my journeyings in high altitudes I have seen most of the symptoms of alcoholism reproduced. I have seen men vomit, I have seen them quarrel, I have seen them become reckless, I have seen them become garrulous, I have seen them become morose. I have seen one of the most disciplined of men fling his arms about on the ledge of a crevasse to the great embarrassment of the guide. I have seen the most loyal companion become ill-tempered and abusive to the point at which I feared international complications would arise."—Lessons from High Altitudes.

The effects of anoxia vary in severity and duration.

Complete prostration may follow the earlier symptoms. If the individual remains at the high altitude the symptoms pass off after a time, as he becomes acclimatized to the low oxygen tension.

CHANGES ASSOCIATED WITH ACCLIMATIZATION. At an altitude of 14,200 feet as at Cerro de Pasco where Barcroft and his party carried out their investigations the barometric pressure is around 440 mm. Hg. The partial pressure of oxygen is therefore about 92 mm. The oxygen tension of the alveolar air is not as far below that of the atmosphere as at sea-level, and varied among the greater number of the party from 55 to 60 mm. Hg. The closer approximation of the atmospheric and alveolar oxygen tensions at high altitudes is due to the increased breathing which results in a more effective ventilation of the air sacs. The increased respiration is brought about through the action of the lowered oxygen tension in the blood. The oxygen tension is slightly lower in the arterial blood than in the alveolar air which indicates that the passage of the gas is due purely to diffusion and not to an active secretion by the pulmonary epithelium. If this occurred, as has been suggested (Haldane), one would expect the arterial oxygen tension to be higher than that of the alveolar air. Alveolar carbon dioxide tension also, as a result of the increased pulmonary ventilation, is lower than that at sea-level; it varied in different individuals of Barcroft's party from 23 to 29 mm. Hg. At 14,200 feet the arterial blood is from 85 to 88 per cent saturated with oxygen (see fig. 149, p. 321).

A marked increase in the number of red cells (see p. 9) and a corresponding increase in hemoglobin content of the blood occur at high altitudes. The blood volume is also augmented. The natives of a mountainous regions have a red cell count of from 6 to 8 million per cubic millimeter. The greater quantity of hemoglobin of course raises the oxygen capacity of the blood and so tends to counteract its lowered oxygen saturation. That is, the *total* oxygen content of the arterial blood tends in spite of the low saturation to rise. Nevertheless, it may not be evident at first sight how a rise in the oxygen capacity is of advantage, for, blood of normal hemoglobin content even when only 80 per cent saturated possesses a quantity of oxygen which is quite adequate for the needs of the tissues. It has already been pointed out, however, that the important factor in supplying the tissues is the oxygen pressure gradient between the plasma in the capillaries and the tissue cells. So then, if there are a greater number of red cells each will be required to give up less of its oxygen store in passing through the capillaries to furnish a given quantity of oxygen (see anoxia due to anemia, p. 359). Consequently the saturation and the oxygen tension of the venous blood will be maintained at a higher level than otherwise would be possible. This means that the mean intracapillary oxygen pressure will also be higher, and as a result the tissues are more effectively supplied with oxygen.

The reduction in the alveolar carbon dioxide results in a corresponding decrease in the carbon dioxide tension of the arterial blood. The ratio $H_2CO_3/NaHCO_3$, which tends to be altered by the loss of carbon dioxide, is adjusted by a decrease in the excretion of acid and ammonia in the urine, a consequent lowering of the "alkali reserve" and depression of the CO_2 dissociation curve (p. 338). The actual pH of the plasma changes little if at all. Up to about 12,000 feet if any change occurs it is toward the alkaline side; above this level the blood reaction shows little further change or tends to return to normal. Lactic acid, which was thought at one time to be produced in excess as a result of the anoxia is actually formed in smaller amounts at high altitudes than at sea-level. Even during severe exercise at 15,000 feet and higher altitudes the lactic acid concentration in the blood is lower than during exercise of comparable severity at sea-level.

Barcroft and his party observed a shift to the left in the oxygen dissociation curve of hemoglobin, i.e., the affinity of hemoglobin for oxygen

was increased. The shift in the dissociation curve is ascribed by Barcroft to an increased alkalinity of the *interior of the red cell*. This increased alkalinity is in turn a direct result of the rise in the number of red cells. The buffering power of the blood is increased through the greater facility offered for the action of the "chloride shift" mechanism (p. 339). In other words, when a given amount of carbon dioxide is liberated by the tissues it is distributed among a greater number of red cells than under normal circumstances; therefore, the alkalinity of each cell is reduced to a proportionately less extent. There have been conflicting reports concerning this question of the shift in the oxygen dissociation curve. Some observers have been unable to confirm Barcroft's finding, while others claim that a shift to the right occurs. The truth appears to be that up to about 14,000 feet the affinity of hemoglobin for oxygen increases, but at higher levels the dissociation curve tends to assume the form found at sea-level, and at altitudes of 19,000 feet there is a definite shift to the right.

One might suppose that an increased circulation rate would be an important adjustment to the rarefied atmosphere whereby an adequate oxygen supply to the tissues would be maintained, but except for a temporary increase during the first few days no change in cardiac output occurs at altitudes of less than 14,000 or 15,000 feet. Above 15,000 feet the greater degree of anoxia results in an increase in the minute volume of the heart. Before acclimatization, the pulse rate during rest increases by from 15 to 20 beats per minute at altitudes between 15,000 and 18,000 feet. At greater altitudes, especially in persons in poor physical condition, the rate may increase above the normal. The acceleration of the pulse, according to Barcroft, is a signal of distress flown by the heart laboring under the effects of the anoxia, and not an indication of an increased minute volume. The blood pressure shows little or no change up to 15,000 feet; a small rise may occur at higher altitudes. For the effect of anoxia on the coronary circulation, see p. 279).

In the Andean expedition the diffusion coefficient (p. 314) of oxygen was not found to be increased to more than a slight extent during acclimatization yet those members of the party who had high diffusion coefficients to start with suffered less from mountain sickness than those in whom the coefficient was low.

Those who have lived all their lives at very high altitudes (around 14,000 feet) have a larger vital capacity than dwellers at sea-level. Barcroft reports that a native of Cerro de Pasco of 5 feet, 3 inches in height had a chest of a man of 6 feet. Moderate altitudes—up to about 7500 feet appear to have little or no effect upon the chest development.

Though anoxia is the most serious effect of high altitudes with which the mountain climber or aviator has to contend, rapid ascents, as by airplane, cause other important physiological disturbances which should be mentioned, namely, (1) expansion of gases in the gastro-intestinal tract, (2) aeroembolism and (3) pressure disturbances in the ears (p. 1044).

Expansion of gases in the gastro-intestinal tract. Like the gases of the atmosphere those in the stomach and intestine increase in volume in proportion to the reduction in pressure. Gas having a volume of 1 liter at sea level expands to 2 liters at the pressure (375 mm. Hg) existing at 18,000 feet, to 4 liters at 34,000 feet and to 6 liters at 42,000 feet (pressure 128 mm. Hg). Distension of stomach and intestine will result unless the abdomen is supported by a belt or by other means, or the gases are freely evacuated. In rapid ascents distress or even severe pain results if there is any hindrance, as by an obstruction in the colon, to the ready passage of flatus.

Caisson disease—Compressed air illness—Aeroembolism—"the bends"

Caisson disease and the corresponding condition that occurs during rapid ascents to high altitudes may be conveniently described here. Caisson disease occurs in deep sea divers or workers in caissons when they pass too quickly from the high pressure in which they have been confined to the ordinary pressure of the atmosphere.

When an animal is subjected to high atmospheric pressures the amount of the respiratory gases in the blood plasma and tissues increases in proportion to the raised partial pressures of these gases in the alveolar air. Very high pressures are well tolerated and no harm is caused by the increased amount of oxygen or nitrogen provided that they remain in solution.

The cause of the symptoms in Caisson disease are the bubbles of gas which form when the atmospheric pressure is suddenly lowered. These bubbles which are composed mainly of nitrogen act as emboli (*aeroembolism*) and the symptoms produced depend on the site where such emboli lodge—lungs, brain, heart, anterior or posterior spinal roots, etc. There may be extensive capillary hemorrhage and the frothing of the blood may interfere with cardiac action and with the flow of blood in the blood vessels. The amount of gas retained by an individual during the compression is proportional not only to the partial pressure of the gas but also to the amount of fatty tissue in which nitrogen is selectively soluble. Symptoms are not

produced unless the *excess* pressure is more than $1\frac{1}{2}$ atmosphere, however rapid is the rate of decompression or however long is the exposure to the higher pressure. Apparently the supersaturation of the tissues is not great enough and the volume of nitrogen liberated upon decompression is therefore not sufficient to form bubbles or at any rate to cause damage.

Aeroembolism can be avoided by slow decompression, the excess nitrogen being then gradually eliminated in the expired air. But slow decompression is inconvenient and tedious. The fact just mentioned that rapid decompression from a pressure of a little over 2 atmospheres does not cause symptoms suggested to Haldane and his associates that halving the pressure whatever its height, i.e., a reduction from 4 atmospheres to 2 or 6 to 3 could be carried out rapidly and with safety. This is the basis of the method of decompression now generally employed. Decompression is carried out in stages or steps rather than continuously, the air pressure to which the subject is exposed at each stage being just half the pressure at the preceding stage.

In *military airplane flights* the airman may be required to ascend to upwards of 30,000 feet (226 mm. Hg) within a few minutes. He is then subjected to rapid decompression, not, as is the deep sea diver, from a high pressure to atmospheric pressure, but from atmospheric pressure to a pressure of about $\frac{1}{2}$ of an atmosphere. But the same general principles apply and similar results follow as those outlined in the preceding section. A reduction in pressure from 1 atmosphere to $\frac{1}{2}$ of an atmosphere would correspond to a reduction from 3 atmospheres to 1 atmosphere. At 20,000 feet (350 mm. Hg) the pressure is little more than halved and aeroembolism would not be expected to occur. The effects of aeroembolism in flyers take the form most commonly of severe pain in one or more of the large joints (air-bends), itching of the skin or cutaneous sensations of heat or cold. Other more serious symptoms, e.g., paralysis due to the formation of bubbles in the spinal cord or brain, intense burning pain in the chest, or pulmonary edema may sometimes occur. The symptoms are, however, rarely as severe as those occurring in compressed air illness; the effects are not, as a rule, permanent and fatalities seldom result. They are quickly relieved in most instances by descending at once to lower levels. Aeroembolism is rare even with very rapid decompression (equivalent to ascents of 12,000 feet per minute) at altitudes below 30,000 feet. But above this apparently critical level they may result from a rate of ascent of only 200 feet per minute. The rate of ascent necessary to induce aeroembolism becomes progressively slower with increasing altitude; at 40,000 feet bends may result from a rate of only 80 feet per minute. The most effective way to prevent or diminish the effects of rapid decompression is to have the airman breathe pure oxygen or an oxygen-helium mixture (oxygen 21 per cent, helium 79 per cent) for a couple of hours

before the flight and thus induce the elimination of nitrogen from his tissues. Exercise also encourages the elimination of nitrogen.

ANOXIA DUE TO ABNORMALITIES OF THE PULMONARY MECHANISM

PNEUMONIA

In *lobar pneumonia* the oxygen saturation of the arterial blood varies in different cases from normal to less than 70 per cent. The signs and symptoms of anoxemia usually appear when the saturation is around 85 per cent. Cerebral symptoms, e.g., sleeplessness and delirium, cyanosis and dyspnea increase with the oxygen desaturation and a saturation of less than 80 per cent is associated with a very high mortality. In 33 cases reported by Stadie with a saturation as low or lower than this only 1 recovered. In lobar pneumonia the carbon dioxide content of the arterial blood is reduced on the average by about 15 per cent (Meakins and Davies). The "alkali reserve," however, is normal or only slightly reduced, the carbon dioxide dissociation curve not differing significantly from the normal. The blood pH may in some cases be shifted slightly toward alkalinity. From these findings it appears that there exists a partially compensated alkalosis, induced by the hyperventilation (blowing off of carbon dioxide). In severe cases the excessive elimination of CO₂ may cause a rise in the respiratory quotient to above unity. The increased ventilation of the alveoli also increases the percentage of oxygen in the alveolar air but this fact cannot, as we shall see presently, increase appreciably the oxygen in the arterial blood.

In *bronchopneumonia* a higher degree of oxygen desaturation of the arterial blood is usually present than in the lobar type. The cyanosis may be extreme. There is often *retention* of carbon dioxide when a rise in plasma bicarbonate results, to compensate, in part at least, the gaseous acidosis. The carbon dioxide content of the arterial blood may be 80 volumes per cent or more and the carbon dioxide dissociation curve well above the normal level.

The causes of the anoxia (anoxemia) in pneumonia

The main factors concerned in the production of the anoxemia are (a) the passage of blood through unaerated portions of the lung and (b) shallow breathing. The oxygen unsaturation is not due to any change in the hemoglobin itself (e.g., the formation of methemoglobin) since the blood of pneumonia patients has a normal oxygen capacity.

The oxygen dissociation curve at a given carbon dioxide tension is not appreciably different from that of normal persons.

In *lobar pneumonia* during the stages of engorgement and red hepatization the alveoli of the affected portion of the lung are poorly aerated. Mucus blocks the bronchioles and the *air spaces* are filled or their walls coated with exudate. But a large proportion of the vessels of these unaerated regions are still pervious. Consequently blood traversing such areas must remain poor

FIG. 163. X-ray photograph of lung (injected with barium) from a case of lobar pneumonia (after Gross). *Upper right hand area.* Consolidated area—red hepatization. The main vessels are constricted and the fine vascular structure is less dense than in the normal lung. *Lower right hand area.* Consolidated area—gray hepatization. The main vessels are patent but the fine vessels have been occluded. *Lower left hand area.* Healthy portion of lung except for compensatory congestion; the vessels are dilated.

oxygenated or entirely venous. This blood with a low oxygen saturation and a high carbon dioxide content mixes with blood which has passed through aerated regions. The general arterial blood therefore has its oxygen saturation reduced in proportion to the amount of unsaturated blood with which it is mixed (see also Shunt, p. 371). When the pneumonic area passes into the stage of gray hepatization the vessels of the affected lobe become obliterated to a large extent and the pulmonary blood then passes through aerated regions (fig. 163). That is, the arterial blood is no longer

initiated by blood from non-aerated areas. Therefore in a typical case of lobar pneumonia when the disease is confined to a single large area and the breathing is not shallow there is little anoxemia at this stage. If however, bronchopneumonic areas co-exist, the respiratory functions will be affected as described below. (See Oxygen Therapy, p. 375.)

In *bronchopneumonia*, patches of lung tissue are cut off from their air supply. The fine bronchioles become plugged with mucus, groups of alveoli become filled with exudate and the alveolar walls are edematous and thickened. Yet, obliteration of the vessels to any great extent does not occur. Blood continues to flow through unaerated areas. This blood which is highly venous, mixing with that from aerated alveoli lowers the saturation of the general arterial blood.

SHALLOW BREATHING. In pneumonia the breathing is frequently very rapid and shallow. Instead of the tidal air being around 500 cc. as in health it may be reduced to 250 cc. or less. It will be recalled that 150 cc. are required to fill the anatomical dead space, therefore only 100 cc. will enter the air sacs of the healthy parts of the lung. We have seen that the expansion of the lungs is not equal in all its parts (p. 490). The alveoli towards the hub of the radiating rays expand less than those near the periphery. Those parts, such as the apex, which are indirectly expanded have even in health a tendency to be ventilated less than those which are directly expanded. In shallow breathing, these differences are greatly exaggerated. Though the volume of the tidal air is only half the normal, the total quantity of air breathed per minute (minute volume) is, as a result of the increased respiratory rate, much greater than normal. Since a proportion of the alveoli are very poorly ventilated or not at all, owing to the unequal expansion of the lung, those in other areas are over-ventilated. The O_2 tension in the latter is therefore raised. But so far as the oxygenation of the blood is concerned the over-ventilation of some alveoli cannot make up for the under-ventilation of others. We know that the hemoglobin is nearly saturated already at the ordinary alveolar oxygen tension of 100 mm. Hg (see footnote p. 317). As already mentioned the dissociation curve of hemoglobin in pneumonia does not differ appreciably from that in health and the most therefore that could be expected from a rise in the alveolar O_2 tension would be an increase of less than 5 per cent in oxygen saturation of the blood traversing over-ventilated regions and a slight increase in the amount of O_2

held in simple solution. In other words, the blood flowing through the poorly ventilated parts of the lung will have a low saturation since the O_2 tension is low, while that flowing through the over-ventilated parts will be little above the normal. The net result will be a low oxygen saturation of the mixed arterial blood.

Matters are different in the case of CO_2 elimination. The shape of the CO_2 dissociation curve which shows a progressive slope throughout the entire range of CO_2 tensions is quite unlike that for oxyhemoglobin (fig. 164). The greater total ventilation results in a lowering of CO_2 tension in the over-ventilated parts of the lung and, conse-

FIG. 164. Carbon dioxide and oxygen dissociation curves. The small rectangles indicate the extent of the variation of the O_2 and CO_2 of the subject's blood when at rest. (From L. J. Henderson.)

quently, in a "blowing off" of CO_2 from the blood circulating through these regions. CO_2 is retained in the blood circulating through poorly ventilated regions. In the patient with lobar pneumonia the amount of CO_2 blown off may exceed that retained; the net result will be a lowering of the CO_2 content of the arterial blood. In bronchopneumonia a larger proportion of the pulmonary blood circulates through non-aerated areas. As a consequence, CO_2 retention is greater, and a normal or a higher than normal CO_2 content of the blood is more usual.

Haldane, Meakins and Priestley produced anoxemia in normal persons by having them breathe into an apparatus which reduced the

volume of the tidal air. As the depth of the breathing became reduced the respiration increased to 100 or more per minute. The CO_2 percentage of the alveolar air fell and the O_2 percentage rose. The shallow breathing artificially induced in this way resembles that seen in pneumonia and other diseased conditions. The administration of oxygen abolished the anoxemia.

The cause of shallow breathing in pneumonia. Pleuritic pain, by restricting the respiratory excursions, may result in this type of breathing. In other instances it appears to be of a reflex nature resulting from the inflammatory process which, through a reduction in the distensibility of the pulmonary tissue, exalts the sensitivity of the afferent vagal endings in the alveolar walls. Thus the inspiratory movement is terminated before a full excursion has been completed (see Hering-Breuer reflex, p. 345). In support of a reflex origin the experiments of Dunn and of Binger, Brow and Branch may be mentioned who produced this type of breathing in animals by the intravenous injection of potato starch granules. These, acting as small emboli, plugged the pulmonary capillaries. The rapid shallow breathing was immediately abolished by section of the vagi or prevented if the nerves had been cut before the injection. Breathing a mixture rich in carbon dioxide with intact nerves also restored the respiratory rate and depth to normal—the action of carbon dioxide upon the respiratory center itself overcoming the afferent nervous influence. Also, in pneumonia it has been found that oxygen inhalations, even though they may restore the oxygen saturation of the arterial blood to normal, do not necessarily abolish the shallow breathing—further evidence for the existence of a nervous element in the production of this type of breathing. Shallow breathing may also result from other diseases involving the alveoli, e.g., inflammation by irritant gases (phosgene and chlorine), pulmonary edema, miliary tuberculosis and pulmonary emboli, which would be expected to stimulate afferent nerve endings. It also occurs in certain nervous states, hysteria, certain forms of neurasthenia and sometimes in encephalitis lethargica, but is not seen in lesions involving the bronchi or bronchioles alone, e.g., bronchitis and asthma.

Severe anoxemia, however produced, tends itself through its damaging effect upon the respiratory center to induce rapid shallow breathing, and in any event will exaggerate this type of breathing, since it also tends to increase the sensitivity of the Hering-Breuer reflex. Thus a vicious circle—

shallow breathing inducing anoxemia and the latter reacting to enhance the former—is set up. Shallow breathing induces one of the gravest types of anoxemia, since the cardiovascular system, as well as suffering from oxygen want, is seriously affected by the excessive loss of carbon dioxide (see p. 250). Owing to the narrowed state of the cutaneous vessels the cyanosis is of the pale leaden-gray type (p. 375) and if the anoxia is not relieved, failing circulation adds to the oxygen want (anoxia of the stagnant type). The acapnia would also tend to magnify the oxygen want of the tissues for, as we have seen, the hemoglobin gives up its oxygen less readily at low carbon dioxide tensions.

ASTHMA

This is a paroxysmal disease in which acute oxygen want is caused by a spasm of the smooth muscles of the finer bronchioles. Edema of the bronchiolar mucosa is probably also present. The alveoli are poorly ventilated and some may be completely cut off from their air supply. The high percentage of carbon dioxide and low percentage of oxygen in the alveolar air result in a low oxygen saturation of the arterial blood and the retention of carbon dioxide. The gaseous acidosis is met by the excretion of a highly acid urine and a rise in the "alkali reserve." An intense plum-colored cyanosis develops. The continued stimulating effect of oxygen want and carbon dioxide excess upon the respiratory mechanisms causes violent hyperpnea.

Difficulty is experienced both in inspiration and expiration but since there is a natural tendency for the bronchioles to narrow during expiration and dilate during inspiration the greatest respiratory effort is exerted during expiration. The respiratory muscles contract with great force and the accessory muscles of respiration are brought into play. The expiratory muscles compress the chest and the abdominal muscles contract in the attempt to squeeze the air from the lungs. The intrapulmonary pressure is greatly elevated and the air escapes through the constricted tubes with a distinct wheezing sound. Owing to the difficulty and prolongation of the expiratory phase normal deflation of the lungs cannot occur before the next inspiration ensues. The lungs, therefore, remain almost maximally expanded even at the end of expiration. That is, during the asthmatic paroxysm a very large volume of residual air is present in the lungs (fig. 165). The volume of the tidal air is greatly reduced and corresponds to the vital

capacity at the moment. Since the subject is already exerting the greatest inspiratory and expiratory efforts of which he is capable there can be no supplemental or complemental air. The changes in volume of the over-distended lung are small and not commensurate with the excursions of the thoracic walls. As a consequence, the high value of the intrathoracic negative pressure induced during inspiration causes the structures at the root of the neck to be drawn toward the thoracic cavity to take up the space which the

is fixed in an elevated position, resembling the normal chest in full inspiration. The sternum is prominent and the ribs more horizontal than normally. The anteroposterior diameter of the thorax is as great or greater than the lateral, the chest assuming the so-called barrel shape.

The *sputum* in asthma contains spirals of delicate fibrils (Curschmann's spirals) formed of bronchiolar secretion, diamond shaped crystals (Charcot-Leyden crystals) and eosinophil cells. A substance possessing a histamine-like action has been demonstrated in the sputum by Knott. The blood in asthma shows a great increase in the eosinophil cells (eosinophilia). The effect of the asthmatic paroxysm upon the heart is that of partial asphyxia. A-V conduction may be depressed as shown by some lengthening of the P-R interval in the electrocardiogram or premature beats may occur. The attack appears to cause no permanent damage to the cardiovascular system.

Causation

Asthma often shows a strong hereditary tendency. The bronchiolar spasm may be (a) of a *reflex nature* and due to the stimulation of hyper-sensitive afferent vagal endings in the larynx, or of trigeminal fibers by some nasal abnormality; the bronchoconstrictor impulses travel via efferent vagal fibers, (b) an *allergic phenomenon*, i.e., the result of sensitization to some foreign protein. This is the most common cause of the condition. It is then frequently associated with other allergic conditions, e.g., hay fever, urticaria or eczema either in the patient himself or in members of his family. The foreign protein may be inhaled. Pollens of various grasses and flowers, the dandruff of animals, e.g., horse, cat or dog, or feathers are among the most common excitants; the exciting cause may be some kind of food or the protein of bacteria within the respiratory tract itself may be responsible. The sensitivity of certain individuals to foreign proteins presents many features resembling those of anaphylactic shock in animals. The two conditions are probably in some way closely related. Sudden death may result from the injection of horse serum (e.g., diphtheria antitoxin or anti-tetanic serum) into an asthmatic subject. A guinea pig when injected with a protein to which it has previously been sensitized dies rapidly from anaphylactic shock. The bronchiolar muscle is strongly contracted. The air is trapped so that the lungs are maximally distended and do not collapse when the thorax is opened. Even when the pulmonary tissue is deeply incised the air does not escape

FIG. 165. Diagram showing subdivisions of the lung air in asthma (II) and emphysema (III) compared with the normal (I). A, complemental air; B, tidal air; C, supplemental (reserve) air; D, residual air. The horizontal lines above and below the area representing tidal air in II and III indicate the extent of the respiratory movements. (After Coke.)

lungs are unable to fill. These structures are expelled again during expiration. The veins of the neck and face become engorged. Restricted movements of the lung also greatly reduce the effect of mechanical mixing upon the lung air, the slower process of diffusion being depended upon to a larger extent for the freshening of the alveolar air.

Repeated asthmatic attacks during early life, while the thoracic framework is still soft, produce a characteristic deformity of the thorax. The chest

from the distended lung. This manifestation of anaphylaxis is associated with, perhaps due to, the liberation of histamine into the pulmonary circulation. Several groups of workers agree that histamine appears in the blood promptly after the administration of the antigen and persists for a brief interval. It is well known that anaphylaxis and histamine administration produce almost identical effects in the guinea pig (fig. 166). Histamine producing bacteria have been reported in the bronchial secretions of asthmatics.

The bronchiolar movements are not dependent entirely upon extrinsic autonomic nerves, but are under the control of an intrinsic nervous mechanism.

FIG. 166. Guinea-pig. Reaction of bronchial muscle to 0.01 mg. histamine. (After Thornton.)

Daly found in experiments with perfused isolated lungs that varying the bronchial circulation, through which the pulmonary nerves and ganglia are supplied, caused changes in pulmonary ventilation. He suggests that a disturbance of the intrinsic nervous control of the bronchioles through alterations in its blood supply may play an important rôle in some types of asthma. Attention is thus directed to abnormal vasomotor influences rather than to factors—nervous or humoral—acting directly upon the bronchial musculature.

The treatment of asthma resolves itself into the relief of the paroxysm and the removal of the underlying cause. Adrenaline or ephedrine acts by inhibiting the bronchiolar muscle during the attack. Atropine paralyzes the broncho-constrictor

(vagal) fibers. Of the three drugs, adrenaline is the most effective. In the allergic form of the disease every effort is made to identify the offending protein.

CHRONIC EMPHYSEMA

(Greek *em* + *physema*, a blowing)

The lungs in emphysema are in a state of extreme distension as a result of the enlargement of the air sacs. The latter, however, show fewer alveoli in their walls owing to the atrophy of the inter-alveolar septa. Contiguous air sacs within a lobule coalesce or even adjacent lobules may fuse to form large air spaces. For this reason the total respiratory surface is reduced. The alveolar and capillary walls become thickened and the interstitial pulmonary tissue increased. Many capillaries become occluded. The pulmonary elastic tissue is reduced in amount so that the lungs, when removed from the thorax, do not collapse normally but remain in an overexpanded state. The peripheral lobules, which in health expand to the greatest extent, are those mainly affected in emphysema, the enlarged lobules appearing as blebs upon the surface of the lung.

The chest is what is known as barrel-shaped. The ribs are more horizontal than normally, the thoracic spine is bowed backwards (kyphosis) so that the anteroposterior diameter of the chest is as great as or exceeds the transverse. The position of the chest is one of nearly full inspiration. The mid-position of the diaphragm is at a much lower level than usual and its excursions above and below this level are restricted. The respiration is therefore mainly costal. In some instances the diaphragm is practically fixed or indeed may be drawn up during inspiration (paradoxical movement). As in the paroxysm of asthma the residual air is 2 or 3 times the normal and the complementary air is reduced. The tidal air is normal or only moderately reduced and the vital capacity (fig. 165) is lowered by from 20 to 60 per cent. Owing to the loss of the elasticity of the lung, expiration is no longer simply a passive movement but is aided by a forcible contraction of the expiratory muscles. When the patient is asked to make a deep inspiration he does not expel all the air during the next expiration. A series of respirations occur before the chest returns to its original size. Furthermore, he cannot expel nearly as large a volume of reserve (supplemental) air immediately after a deep inspiration. These phenomena are due to the fact that the inelastic lungs have been over-

stretched and are brought back to their original volume with difficulty.

In emphysema there are anoxemia and retention of carbon dioxide. The oxygen saturation of the arterial blood runs from a little below normal to around 85 per cent. The carbon dioxide tension in the alveolar air in well marked cases is from 50 to 60 mm. Hg (7 to 8 per cent) and the carbon dioxide content of the arterial blood correspondingly high.

The cause of the impaired gaseous exchange is not altogether clear. Thickening of the alveolar and capillary walls has been considered to be a factor. Yet if this were so one would not expect the retention of carbon dioxide which, owing to its greater solubility (30 times that of oxygen) has a much higher rate of diffusion through the pulmonary membrane, to be so much more pronounced than the anoxia. The sharp rebound at the end of inspiration which occurs in the healthy lung causes mechanical mixing of the lung air and is an important factor in the efficient ventilation of the alveoli. The absence of this effect in the emphysematous lung and its greater dependence, in consequence, upon the slower process of diffusion is probably an important factor leading to the defective aeration of the blood. According to Christie, the impaired gaseous exchange is due mainly to the fact that, as a result of the loss of elasticity, the intrathoracic pressure is not distributed evenly throughout the lung. As a consequence, the outlying alveoli which are largely functionless with obliterated vessels are ventilated to a greater extent than the relatively healthy ones more centrally placed. Owing to the shapes of the respective dissociation curves such under-ventilation of the functioning alveoli will tend to have a greater effect in preventing the elimination of CO_2 than in interfering with the absorption of oxygen. Another factor which is probably of importance is the slower rate of diffusion of CO_2 , owing to its larger molecule, in the alveolar air.

The red cell count, hemoglobin percentage, and consequently the oxygen capacity of the blood, are increased above the normal in emphysema. The cyanosis (p. 372) is often pronounced, yet the patient's dyspnea is less than might be expected from his color, often startling, and from the carbon dioxide retention which exists. This is explained by the well established fact that in emphysema the respiratory center is relatively insensitive to carbon dioxide. A normal person when breathing a carbon dioxide rich mixture (8 per cent) increases his pulmonary ventilation by 300 per cent

or more; the breathing of the emphysematous patient on the other hand shows relatively little change as a result of breathing a much stronger mixture (see fig. 167).

Causation

Two factors are concerned in the production of emphysema (a) reduction in the elastic tissue of the lung and (b) increased distention of the alveolar spaces.

FIG. 167. Chart showing the percentile increase in tidal air per minute as the percentage of inspired carbon dioxide is raised. Note that when the normal subject inspires air containing 8 per cent carbon dioxide, the tidal air is increased about 300 per cent, whereas in the emphysematous subject it is increased only about 25 per cent. (After R. W. Scott.)

It is very questionable whether, in the absence of some abnormality of the lung tissue itself, emphysema can result from increased intrapulmonary pressure, such as occurs in those following certain occupations, e.g., glass blowers and the players of wind instruments. The study of groups of men following such occupations does not indicate that emphysema is produced in this way. Emphysema has, however, been induced in animals by stenosis of the trachea or bronchi or by the insertion of a valved apparatus into the trachea which allowed the free ingress of air but offered an obstruction to expiration. It is probable that

in these instances the persistently high intra-alveolar pressure by stretching the lung structures during *inspiration* first caused atrophy of the elastic tissue. During inspiration the air spaces are dilated by the negative pressure upon their outer surfaces. The trapped inspired air causes an ever-increasing distending pressure to be exerted upon the alveolar walls. Inasmuch as the intrathoracic pressure is "less negative" during expiration, a reduction rather than an enlargement of alveolar capacity would result at this time (see p. 297). Asthma and chronic bronchitis⁴¹ which frequently are forerunners of emphysema also, probably, exert their damaging effect upon the alveolar structure during the inspiratory phase. In the former condition the spasm of the bronchiolar muscle exerts a valve-like action (see p. 307). In chronic bronchitis mucous plugs would act similarly. Coughing, it has been supposed, places a strain upon the alveolar walls. But during the phase of coughing when the glottis is closed the alveolar walls are supported. When the glottis opens, the air escapes from the alveoli if the obstructing material has been dislodged, and no strain upon the alveolar wall would result. If, however, the air remains entrapped its sudden re-expansion (rebound), as the pressure in the surrounding pulmonary tissue falls at the end of a cough, may injure the alveolar membrane and start the emphysematous process.

What may be termed a physiological or *compensatory* emphysema occurs when part of the pulmonary surface is reduced as by the collapse of a part or the whole of one lung. This is more in the nature of an hypertrophy. A similar enlargement of both lungs occurs at high altitudes.

A type of emphysema also occurs in the elderly—*senile* or *postural emphysema*—and is secondary to the change in the shape of the thorax which becomes more barrel-shaped and increased in capacity. The lungs enlarge to fill the increased space. This condition is associated with few symptoms. There is little reduction in the vital capacity and the oxygen saturation of the arterial blood is practically normal.

COLLAPSE OF THE LUNG OR ATELECTASIS

(Gk *ateles*, incomplete; *ektasis*, distention)

Any condition which lowers the pressure (atmospheric) within the alveoli or increases the pressure upon the lung surface, i.e., reduces the "negative" intrapleural pressure, may lead to collapse of the lung. Thus pleural effusions, pneumothorax, tumors, etc., pressing from without

or the isolation of the alveoli from their air supply by the obstruction of a bronchus will therefore result in collapse of the lung or of the portion of lung affected. Atelectasis is also the term applied to the condition in the newborn in which, as a result of the blockage of a bronchus or of a group of bronchioles by mucous secretion, or owing to weak inspiratory movements, a portion of lung fails to become distended with air.

When a bronchus or bronchiole in a previously distended lung is obstructed the imprisoned air soon becomes absorbed from the affected alveoli. Collapse of the air sacs cannot take place until this has occurred. Absorption is brought about in the following way, as pointed out by Henderson. The air in the isolated alveoli has a total pressure of 760 mm. Hg (p. 315). The partial pressures are in round numbers, O_2 , 100 mm.; N_2 , 570 mm.; CO_2 , 40 mm. and aqueous vapor, 47 mm. In the venous blood the total pressure is 703 mm., the nitrogen and aqueous vapor being the same as that of the alveolar air, but the partial pressure of oxygen is only 40 mm. and of carbon dioxide 46 mm. An interchange of the latter gases therefore occurs between the alveolar air and the venous blood. It might be thought that the imprisoned air would then be in equilibrium with the blood and no further absorption occur. But the alveolar air loses more oxygen than it gains carbon dioxide whereupon its volume is reduced. The atmosphere acting upon the body surface and through the yielding soft tissues compresses the air so as to maintain its total pressure practically constant at 760 mm. As a result of the absorption of oxygen the percentage and consequently the partial pressure of carbon dioxide and of nitrogen are increased. These gases now diffuse into the blood. The volume of the air is further reduced thereby but its total pressure still remains unaltered. The percentage and therefore the partial pressure of oxygen rises and more of this gas passes into the blood. The process continues in this manner until no air remains, and the walls of the original space are ultimately approximated by the pressure of the atmosphere. Air is absorbed from the pleural cavity or from any other closed cavity of the body in precisely the same way (Henderson and Henderson). The absorption of the air confined within the pleural cavity permits the lung, if the air pressure has caused its collapse, to re-expand (see also p. 31).

The collapse and shrinkage of the lung which results from blockage of a bronchus increases intrathoracic negative pressure, since the closed

Thoracic box is less completely filled. The diaphragm is therefore drawn upwards and uncollapsed portions of the lungs are expanded to a greater extent (compensatory emphysema) in order to fill the unoccupied space.

terial blood will be seriously reduced. Anoxemia, evidenced by cyanosis (p. 372) and dyspnea (p. 353) will result (fig. 168). These will be especially pronounced upon exertion since the unsaturation of the polluting venous blood will be thereby increased.

The congenital malformations responsible for this type of anoxia are:

(1) *Patent foramen ovale* through which a communication persists between the two auricles.

(2) *Patent ductus arteriosus (ductus Botalli)*. In the fetus the pulmonary artery after dividing into right and left branches is continued onwards to open into the aorta. Most of the blood leaving the fetal right heart takes the latter course since the lungs are unexpanded; only a small fraction passes through the right and left pulmonary arteries. At birth the expansion of the lungs diverts the blood from its prenatal course. Normally the ductus arteriosus gradually closes appearing in later life as a mere vestige (ligamentum arteriosum). If it fails to close a passage will be afforded for the transference of blood from the aorta to the pulmonary artery.

(3) *Defects in the interventricular septum*. According to Lundsgaard and Van Slyke about one-third of the venous blood must be shunted before cyanosis appears. The absence of this sign therefore does not preclude the existence of a congenital defect—for the quantity of shunted blood may be simply insufficient to produce a high degree of anoxia. It must also be remembered that the diversion of blood may be from left to right rather than the reverse and anoxia would not result. On account of the higher pressure on the arterial side this is what might be expected. Stenosis of the pulmonary artery, however, commonly co-exists with an open ductus arteriosus. This has the effect of raising the pressure on the right side and favoring the flow of venous blood into the arterial stream. In cases of patent foramen ovale the flow is usually from left to right. The development of a mitral lesion by raising the pressure in the pulmonary circuit may reverse the direction of a flow which had previously been from left to right.

The red cell count in congenital heart disease is frequently above the normal. The influence of this upon the degree of cyanosis is discussed on page 374 et seq.

CARBON MONOXIDE AND CYANIDE POISONING

CARBON MONOXIDE POISONING

References to carbon monoxide poisoning are contained in the earliest medical writings. This gas was used by the Greeks and Romans for the execution of criminals and as a means of committing suicide. Carbon monoxide is today the most important gaseous poison against which

FIG. 168. Diagram (upper) showing the proportion of oxyhemoglobin to reduced hemoglobin in different parts of the circulation in an instance where a portion of the blood passes through unaerated channels (shunt) from the venous to the arterial system. Lower diagram presents a case in which the oxygen unsaturation of the blood is abnormally high in a part of the peripheral capillaries but normal in the arterial blood (stagnant type of anoxia). (After Lundsgaard and Van Slyke.)

SHUNT

It is clear that if a large proportion of the venous blood does not traverse the lungs but is short-circuited from the right to the left heart or directly to the aorta, the oxygen saturation of the ar-

physicians have to contend. During times of peace it accounts for more deaths than all the other gases combined. Carbon monoxide combines with the hemoglobin of the blood and thus renders it unavailable for oxygen carriage. This combination is represented by the following reversible equation:

The affinity of hemoglobin for carbon monoxide is approximately 300 times its affinity for oxygen.

Therefore we may substitute $\frac{300}{1}$ for the ratio

$\frac{\text{ACO}}{\text{AO}_2}$. While it can be shown that carbon monoxide

may seriously interfere with tissue respiration this is probably not an important factor in carbon monoxide poisoning since (1) the concentrations of the gas are seldom sufficient to affect the tissues and (2) the anoxia produced by the lack of oxygen carriage causes death before tissue respiration can be specifically affected by the gas. There are numerous ways of estimating the carbon monoxide content of air or blood. Carbon monoxide in air may be estimated gasometrically with a modified Haldane or with the Van Slyke apparatus. The color produced in blood by the carbon monoxide hemoglobin may be matched with that of a carmine solution and the amount of carbon monoxide hemoglobin estimated in this way (Haldane).

Recovery from carbon monoxide poisoning is usually complete when the exposure has not been too long or the concentration too high. It is important that the carbon monoxide hemoglobin should be broken up as soon as possible since injury to the tissues is produced by the anoxia. It is possible to displace the carbon monoxide by oxygen if the tension of oxygen is sufficiently high and that of carbon monoxide low. Mixtures with a high percentage of oxygen and from 6 to 7 per cent carbon dioxide which, as well as acting as a stimulus to the respiratory center reduces the affinity of carbon monoxide for hemoglobin, are used in the treatment of this condition. Intravenous injections of methylene blue have been advocated but are valueless. Methylene blue accelerates oxidation in the tissues; the difficulty in carbon monoxide poisoning, however, is not lack of oxygen utilization but deficiency in the carriage of oxygen by the blood. By forming methemoglobin the dye has actually just the opposite effect. Carbon monoxide, as well as its action in displacing oxygen from hemoglobin, has histotoxic properties, inhibiting the tissue respiratory enzymes.

This fact has no practical bearing, however, upon carbon monoxide poisoning in man, for the concentrations at which such action occurs is many times greater than could ever occur in the body.

CYANIDE POISONING

The mechanism of production of asphyxia by cyanide is quite different from that of carbon monoxide. There is no interference with oxygen carriage by cyanide but there is inhibition of tissue respiration. Cyanide apparently combines with one or more of the enzymes which are responsible for normal tissue respiration (see p. 323). It follows from this that any antidote for cyanide poisoning must have one of two actions. Either the cyanide must be removed or detoxified or the inactivated catalyst must be replaced. Methylene blue does act as a catalyst for certain biological oxidations and this led to its use as an antidote for cyanide poisoning. When methylene blue is given to the intact animal there is a marked rise in body temperature which is due to increased metabolism and not to diminished heat loss. The evidence is satisfactory that methylene blue will reverse the inhibiting effects of cyanide on cellular oxidations. This fact has been established from investigation on a great number of tissues. Sahlin in 1926 provided the first experimental demonstration that methylene blue antagonizes the action of cyanide in the intact animal. He used rats and the observation has been confirmed on other animals—dogs, rabbits, mice. The evidence suggests that methylene blue acts by removing the cyanide from tissue. Methylene blue and cyanide do not combine directly but methylene blue forms methemoglobin and the methemoglobin combines with the cyanide to form cyanmethemoglobin. The cyanmethemoglobin is relatively non-toxic and is broken down slowly, the detoxification probably being brought about by conversion by the cyanide to thiocyanate (Smith and Malcolm). Other substances which form methemoglobin (Hug; Wendel) such as sodium nitrite, amyl nitrite, pyrogallol, etc., are also effective in the treatment of cyanide poisoning. Such methods of course are limited by the quantity of hemoglobin that can safely be converted to methemoglobin.

A number of sulphur compounds have been found effective in cyanide poisoning. Chen, Rose and Clowes showed that sodium thiosulphate and sodium tetrathionate may protect dogs against as much as three lethal doses of cyanide.

CYANOSIS

(Greek, *cyanos*, blue)

Cyanosis may be defined as the diffuse, dusky or bluish color imparted to the skin by the presence in the blood of the superficial capillaries (subpapillary venous plexus, see p. 266) of re-

duced hemoglobin above a certain definite amount.³ It seems scarcely necessary to state that the retention of carbon dioxide in the blood has no *direct* effect upon the production of cyanosis. The blue color of the skin depends fundamentally upon the *absolute* amount of reduced hemoglobin in the capillary blood and *not* upon the *relative proportions* of reduced and oxyhemoglobin. For example, in anemia the hemoglobin content of the blood may be only 20 per cent of the normal. In the capillary blood all of this might be in the reduced form yet cyanosis would not result, since the absolute amount of reduced hemoglobin (i.e., "blue pigment") would be insufficient to produce any blue discoloration. On the other hand, in polycythemia the hemoglobin may be 100 per cent above normal. Cyanosis will occur when the hemoglobin of the capillary blood is only 20 per cent reduced, for the absolute concentration of reduced hemoglobin will then be raised to threshold value. The greater quantity of the bright-colored oxyhemoglobin present exerts little or no influence; that is, it does not, as might be expected, tend to neutralize the color effect of the reduced hemoglobin.

Normal blood contains about 15 grams of hemoglobin per 100 cc. Lundsgaard found that the capillary blood must contain approximately 5 grams of reduced hemoglobin per 100 cc. before cyanosis will appear. Three-fourths gram of hemoglobin takes up 1 cc. of oxygen. So, blood containing 15 grams of hemoglobin per 100 cc. can take up $\left(\frac{15}{0.75} = \right)$ 20 volumes per cent of oxygen. Five grams of hemoglobin absorb $\left(\frac{5}{0.75} = \right)$ 6.7 cc. of oxygen, i.e., 5 grams of reduced hemoglobin are formed when 100 cc. of blood gives up 6.7 cc. of oxygen. Therefore cyanosis would be expected to appear when the blood in the capillaries has lost on the average 6.7 volumes per cent of oxygen, that is, when the hemoglobin is 6.7 volumes per cent unsaturated. As a result of certain modifying factors (p. 375)

³The presence of abnormal compounds of hemoglobin, e.g., methemoglobin and sulphohemoglobin, resulting from the action of various toxic substances, causes a type of cyanosis (enterogenous cyanosis), but these will not be considered here (see p. 44). Cyanosis may result from anoxia of either the anoxic or stagnant type. It obviously cannot occur in the anemic type, which is due essentially to a low hemoglobin concentration, in the histotoxic type in which the hemoglobin gives up less of its oxygen store than in health, nor in the anoxic and stagnant types if a severe grade of anemia exists.

the precise level of capillary unsaturation at which cyanosis makes its appearance varies in different cases between 6 and 7 volumes of oxygen per cent.

The oxygen unsaturation of the capillary blood does not of course occur abruptly at the arterial end but is progressive from point to point along the course of the vessel. The loss of oxygen may be uniform from the arterial to the venous end of the capillary as shown in Curve I, figure 169, or the desaturation may occur mainly toward the venous end (Curve II) when the capillary blood would approximate arterial blood in its content of reduced hemoglobin. Under other circumstances the greatest oxygen loss may occur toward the arterial end (Curve III) when the unsaturation of the capillary blood would approach that of venous blood. It is not possible to obtain data from which the true curve may be drawn. The simplest of these curves (Curve I) is assumed and the average unsaturation of the capillary blood is taken

FIG. 169. Diagram showing hypothetical variations in the shape of the reduction curve of oxyhemoglobin during the passage of the blood through tissue capillaries. (After Lundsgaard and Van Slyke.)

as midway between that of arterial and venous bloods respectively. Thus

$$\frac{A + V}{2} = C$$

where A and V represent the unsaturation in volumes per cent of arterial and venous bloods respectively and C the mean unsaturation of the capillary blood.

For example, in a normal person the arterial unsaturation is 1 volume per cent (19 volumes per cent saturation), another 5 volumes per cent are given up in the capillary, the venous unsaturation is therefore 6 volumes per cent. So

$$\frac{1 + 6}{2} = 3.50 \text{ volumes per cent average unsaturation of capillary blood}$$

$$(3.5 \times 0.75 = 2.5 \text{ gram reduced Hb})$$

We have seen that the average unsaturation of the capillary blood must be between 6 and 7 volumes

per cent (approximately 5 grams of reduced Hb) before cyanosis appears. This degree of unsaturation of the capillary blood may be brought about either by an increase in the arterial unsaturation (anoxic type of anoxia) or as a result of a greater amount of oxygen being lost from the blood in its passage through the capillaries (stagnant type of anoxia). That is, by an increase in the venous unsaturation (V) alone. In order to produce an average unsaturation of from 6 to 7 volumes per cent in the capillary blood the arterial unsaturation would need to be from 4 to 4.5 volumes per cent, or the unsaturation of the venous blood—that in the arteries being normal—11 to 13 volumes per cent. Meakins and Davies found that when the veins of the arm were obstructed in normal individuals cyanosis was just detectable when the venous blood reached an unsaturation of 11.4 volumes per cent.

These facts may be clarified by examples. If the blood as it leaves the lungs contains only 15.5 volumes per cent of oxygen, i.e., if it has an unsaturation of 4.5 volumes per cent and the tissues abstract the usual quantity of oxygen, namely 5 volumes per cent, the unsaturation of the venous blood will be 9.5 volumes per cent and that of the capillary blood

$$\frac{4.5 + 9.5}{2} = 7 \text{ volumes per cent}$$

$$(7 \times 0.75 = 5.2 \text{ grams Hb}).$$

If on the other hand the arterial unsaturation is around the normal value of 1 volume per cent but as a result of slowing of the circulation each unit volume of the blood gives up a greater quantity of oxygen, and the venous unsaturation is increased to say 13 volumes per cent, the average unsaturation of the capillary blood will be

$$\frac{1 + 13}{2} = 7 \text{ volumes per cent}$$

In either of these instances slight cyanosis would be expected to appear.

Let us now consider what occurs when the hemoglobin percentage is above or below the normal value respectively.

In *anemia* the hemoglobin is below normal and the oxygen capacity of the blood is correspondingly lowered. If the hemoglobin content be only 30 per cent of the normal, the volumes per cent of oxygen in the arterial blood, though the latter be fully saturated, will be only about 6 volumes per cent, i.e., the quantity of hemoglobin in 100 cc.

of blood is less than 5 grams. It is obvious that such a person could not become cyanosed even if as a result of defective oxygenation of the blood or of slowing of the circulation, all his hemoglobin were in the reduced state. A patient whose hemoglobin was, say, 60 per cent (oxygen capacity 12 volumes per cent) would, like one with a normal hemoglobin content, become cyanosed when his arterial blood reached an unsaturation of about 4.5 volumes per cent, that is when his capillary blood had an average desaturation of around 7 volumes per cent. But the oxygen want of the anemic subject would be greater than that of the subject with a normal hemoglobin content since in the case of the former 4.5 volumes per cent constitute nearly 40 per cent of the oxygen capacity of his blood. In a less enlightened age when bleeding was resorted to for the relief of cyanosis, the brilliant success of that procedure is not to be wondered at—nor that the patient died. In the stagnant type of anoxia the unsaturation of the venous blood of a subject with 60 per cent hemoglobin content could not reach the value necessary to produce cyanosis until all the hemoglobin was in the reduced state. Thus $\frac{1 + 12}{2} = 6.5$ volumes per cent unsaturation of the capillary blood.

In *polycythemia*, in which the hemoglobin content is, say, double the normal (oxygen capacity 40 volumes per cent), cyanosis occurs in very mild degrees of anoxemia. At an arterial unsaturation of 4.5 volumes per cent the polycythemic subject would have the same degree of cyanosis as an ordinary person with this quantity (5 grams of reduced hemoglobin in his blood. But in the polycythemic subject with a hemoglobin content of 200 per cent, 4.5 volumes per cent is only 1 per cent of the oxygen capacity of his blood; in the person with a normal hemoglobin content it constitutes 22.5 per cent. The oxygen want in the former would be relatively slight as compared with that of the latter. Or put in another way and including the anemic subject—if the anoxemias were of the same degree in each, the anemic person would show little or no cyanosis; the polycythemic, a cyanosis of high degree and the normal subject a color intermediate in intensity. In a person with an abnormally high blood count a degree of slowing of the peripheral blood flow which would be without effect upon one possessing a normal hemoglobin content will result in cyanosis. Thus in regions such as the face, ear lobes and hands, where the cutaneous vessels are wide

filled with blood, cyanosis is readily induced in the polycythemic subject by exposure to cold. In certain conditions associated with arterial anoxemia, e.g., emphysema (p. 368) and congenital heart disease the red cell count is increased and the cyanosis, in consequence, enhanced.

The factors which influence the depth of cyanosis caused by a given quantity of reduced hemoglobin

(a) *The state of cutaneous capillaries.* When these are dilated more of the dark colored blood will be present in the skin than when they are constricted. In the former instance the cyanosis will of course be more pronounced. Increased carbon dioxide tension in the blood causes capillary dilatation, therefore, when retention of this gas accompanies oxygen want as in obstruction of the trachea, emphysema, venous congestion of superficial regions, etc. the cyanosis is intense. When, on the other hand, the carbon dioxide tension is low the cutaneous vessels are constricted. In the anoxemia resulting from rapid shallow breathing (p. 365) therefore the cyanosis tends to be of a pale leaden or heliotrope hue.

(b) *Pigmentation and thickness of the skin.* These factors obviously will modify the depth of the cyanotic color. Cyanosis is more clearly evident in regions where the skin is thin and unpigmented. The yellow discoloration of the skin caused by an excess of bilirubin in the blood (jaundice) tends to modify the cyanotic tint, but since the former stains the skin itself, while the discoloration due to reduced hemoglobin is confined to the capillary vessels, jaundice is likely to be just as intense in regions where the skin is thick as in those where it is thin. The cyanotic discoloration can be temporarily abolished by pressure upon the skin whereas the icteric staining cannot. Cyanosis does not appear in the conjunctivae but these are deeply colored in jaundice.

OXYGEN THERAPY

In combating certain forms of anoxia oxygen administration is a measure of the utmost value. The suitability of a given case for oxygen treatment is dependent upon certain quite definite principles which must be clearly understood. It is not to be expected that anoxia of the stagnant or anemic type would be materially benefited by such therapy since in these the arterial blood is already nearly fully saturated. The most that could result would be an increase in the quantity of oxygen held in simple solution and an unim-

portant rise in the oxygen saturation of the hemoglobin. Nor would anoxia due to a shunt of blood from the right to the left side of the heart (p. 371) or through a similarly completely unaerated portion of the lung be benefited by oxygen inhalations; it is not possible to make the blood supplying healthy and well aerated alveoli absorb any important amount of *extra* oxygen and so compensate for the shunted venous blood (p. 364).

When, however, the diffusion coefficient of oxygen (p. 314) through the alveolar membrane is reduced as a result of edema, thickening or a coating of fluid, oxygen administration by raising the pressure of the gas in the alveolar air will increase its rate of diffusion across the pulmonary epithelium. The oxygen saturation of the blood flowing through the damaged pulmonary tissue is increased.

Consequently, in broncho- or lobar pneumonia when such changes are responsible for the anoxemia, or in pulmonary edema whether from cardiac, pulmonary disease or gas poisoning, the success of oxygen administration is often spectacular. Anoxemia increases the permeability of the pulmonary epithelium to fluids and, consequently encourages edema formation. In other words, a vicious circle is established—edema inducing anoxemia and the latter increasing the edema—which is broken by oxygen administration. It is difficult for one to know the conditions which prevail in the lung in any given case before the treatment has been instituted. The relief of cyanosis, the lessening of restlessness or delirium and of the other signs of anoxemia in response to the treatment indicate that it is effective and, consequently, that the oxygen want is not due to a shunt of blood through channels inaccessible to a high pressure of oxygen.

Anoxemia due to rapid *shallow breathing* is relieved by oxygen treatment since the oxygen tension of poorly ventilated alveoli is raised thereby. The shallow breathing itself is likely to persist since it is primarily due to the local process in the lung acting upon the nerve endings rather than to the anoxemia. Therefore this type of breathing could, no more than the pulmonary lesion itself, be expected to be abolished by oxygen treatment. Nevertheless, since shallow breathing is aggravated by oxygen want it will be ameliorated by oxygen treatment—the vicious circle is broken. Yandell Henderson is a strong advocate for the use of carbon dioxide in combination with oxygen in such cases for the

purpose of deepening and slowing the respirations. That is, the chemical factor in respiratory control is employed to overcome the nervous element—the Hering-Breuer reflex. The prevention of acapnia also removes a hazard to the circulatory functions. Carbon dioxide inhalations alone constitute a valuable measure for the prevention of secondary pneumonias, e.g., post operative, and of pneumonia of the new-born. The high concentration of carbon dioxide in the inspired air favors full expansion of the lung and so circumvents bronchial occlusion and atelectasis.

Oxygen administration is also of definite value in congestive heart failure. This is so, even though anoxemia is absent or of very mild degree. The beneficial effect in such instances is difficult to explain; it is possible that the increased oxygen tension of the blood induced by the treatment exerts a direct specific effect upon the cardiac muscle.

Methods of oxygen administration

Pure oxygen or oxygen (93 per cent) and carbon dioxide (7 per cent) is supplied from a storage cylinder. The old method of administration, namely, the delivery of the gas by means of a funnel held in front of the patient's face and connected by tubing to the oxygen supply, is practically worthless; most of the gas is wasted. In modern methods the patient is placed in an air-tight chamber or the upper part of his body in an oxygen tent. The latter as compared with the former method is much less expensive, more convenient and just as effective (fig. 170). The concentration of oxygen in the atmosphere of the tent is raised to and maintained at from 40 to 60 per cent according to the features of the particular case. The administration should be con-

tinuous. It should be instituted early and before anoxemia due to cardiac involvement and the consequent slowing of the circulation has been added to the anoxemia caused by the pulmonary condition. It should be remembered that very high concentrations of oxygen are definitely toxic to animals and plants and that even concentrations of 70 or 80 per cent may be injurious to the pulmonary epithelium. When carbon dioxide is employed with oxygen its concentration in the tent air is maintained at around 4 or 5 per cent.*

FIG. 170. Photograph of the Barach-Davidson oxygen tent.

Helium (atomic weight 4, density $\frac{1}{7}$ that of nitrogen) is lighter than any other gas except hydrogen. Barach has applied this physical fact to reduce the respiratory effort in asthmatic attacks, in those suffering from laryngeal or tracheal obstruction and in certain other types of dyspnea. A gas mixture is used in which helium is substituted for nitrogen (oxygen 21 per cent, helium 79 per cent). For the relief of anoxemia the oxygen percentage may be increased to between 30 and 40 per cent.

* The patient's own breath adds from 1 to 2 per cent to the atmosphere of the tent.

SECTION IV. THE EXCRETION OF URINE

CHAPTER XXXVI

URINE FORMATION: THE STRUCTURE OF THE KIDNEY; THEORIES OF RENAL FUNCTION; VOLUME AND COMPOSITION OF THE URINE

THE STRUCTURE OF THE HUMAN KIDNEY

THE NEPHRON. This is the functional unit of the kidney. It comprises (1) the *renal (or Malpighian) corpuscle*, and (2) the *renal tubule*, which is divisible into (a) the proximal convoluted tubule, (b) the loop of Henle, and (c) the distal convoluted tubule. There are about 1 million nephrons in each human kidney (fig. 172).

(1) The **RENAL CORPUSCLE** consists of what appears to be a twisted skein of capillary channels—the *capillary tuft* or *glomerulus*—which in development has become invaginated into the upper blind end of the primitive renal tubule. The narrow, funnel-like cavity resulting from this invagination, and which almost completely surrounds the capillary tuft is known as *Bowman's capsule* (fig. 171). The capsular wall therefore consists of a *visceral* and a *parietal* layer. The former is a delicate membrane of flat cells. It envelopes each capillary loop and blends with the vascular wall. This layer becomes folded upon itself and continuous with the parietal layer at the point where the afferent and efferent vessels (see below) enter and leave the glomerulus. The cells of the parietal layer are for the most part squamous in type but become cuboidal near the point where the capsule empties into the tubule. The renal corpuscle measures about 200 microns in diameter. The total surface of the capillary loops of both kidneys is about 1.5 square meters. The renal corpuscles and the convoluted tubules lie in the cortex of the kidney. •

The **PROXIMAL CONVOLUTED TUBULE** is a tortuous tube (about 55 μ in diameter and 14 mm. long) lying in close relation to the renal corpuscle, and into which the latter empties. Its walls are composed of a single layer of cuboidal cells which differ from those lining other parts of the renal tubule in possessing delicate vertical striations at their free borders—the *brush or bristle border*. This appearance is suggestive of the striations seen in the epithelial cells lining the small intestine (Cowdry). The basal portions of the cells show a reticulum of protoplasmic threads radially arranged—the so-called *rods*. The length of the proximal tubule when uncoiled is some 15 mm. Its lumen varies in diameter from 15 to 25 microns in accordance with the quantity of fluid passing through it. The combined area of the 1,000,000 proximal tubules in a human kidney is nearly 1 square meter.

HENLE'S LOOP follows the proximal convoluted tubule and consists of a *descending* and an *ascending* limb, both of which lie for the most part within the renal medulla. The proximal two-thirds of the descending limb, though it follows a nearly straight or a moderately tortuous course, has about the same diameter as that of the proximal convoluted tubule and is lined by similar cells. The distal third of the descending limb becomes greatly narrowed and is lined by clear flat cells. The function of this part of Henle's loop is not definitely known, but it has been suggested that it serves to regulate the pressure of fluid within the tubule. Beyond the narrowed portion the tubule (ascending limb) widens again to its previous diameter. This portion is lined by cuboidal or columnar epithelium and is continued into the distal convoluted tubule. The average length of Henle's loop is about 16 mm.

The **DISTAL CONVOLUTED TUBULE** resembles the proximal convoluted tubule and lies coiled in close relation to the renal corpuscle. Its cells, however, have no brush border but resemble those forming the wide portion of the ascending limb of Henle's loop. Its length when uncoiled is about 5 mm. The distal tubule comes into contact over a limited area with the wall of the afferent vessel just before the latter enters the glomerulus. At this point the lining cells of the tubule assume a columnar shape; their nuclei are densely packed. The whole structure has a plaque-like appearance and is known as the *macula densa*, the term first applied to it by Zimmerman. This part of the afferent arteriole also undergoes a conspicuous structural change (p. 379). The distal convoluted tubule drains into the collecting duct system.

The length of a single nephron when straightened out is between 1½ and 2 inches, and a conservative estimate of the total length of the tubules of both kidneys from Bowman's capsule to the first collecting duct is some 45 miles. The total tubular surface cannot be far from 6 square meters.

A **SYSTEM OF COLLECTING TUBULES** conveys the urine to the kidney pelvis. These tubules are merely conduits and apparently possess no other function. The smallest of the collecting tubules (the *initial* or *connecting tubules*) receive urine from the distal convoluted tubules. Several connecting tubules from neighboring nephrons join to form a larger channel. Through a succession of such unions of smaller ducts and the creation of larger ones, relatively large short tubes—the *papillary ducts* (or *ducts of Bellini*)—are

FIG. 171. Upper drawing, cross section through the convoluted tubule of a dog's kidney showing brush border (From Maximow and Bloom.) Lower drawing, diagram of Malpighian corpuscle. (After Cushny.)

FIG. 172. Diagram of the tubules and blood supply of the kidney. P.C.T. = proximal convoluted tubule; D.C.T. = distal convoluted tubule.

finally formed which open into the renal pelvis at the apices of the papillae (fig. 172).

BLOOD SUPPLY. The renal artery upon entering the hilus of the kidney breaks up into numerous branches—

interlobar arteries—which pass outward between the renal pyramids to the junction of the cortex with the medulla. Here they turn to follow a more horizontal course and form arterial arches across the bases of the pyramids. From these vessels—called *arcuate arteries*—arise the *interlobular arteries* which run outwards through the cortex for variable distances and give origin to a series of small twigs. Each of the latter with few exceptions enters a renal corpuscle and constitutes the *afferent vessel* of the glomerulus. The afferent vessel throughout the greater part of its course has the features of an arteriole; it contains muscle fiber and has a diameter of about 50 microns. Upon entering the renal corpuscle and breaking up into a limited number of primary and secondary branches it gives rise to a leash of some 50 capillary loops which constitute the glomerular tuft. There is no anastomosis between any of these loops, and each is enveloped in a prolongation of the visceral layer of Bowman's capsule, much as the small intestine is covered by its serous coat, or as Vimtrup expresses it, "as a finger is covered by a glove." Nothing therefore separates the blood in each capillary from the cavity of Bowman's capsule except two delicate membranes which together have a thickness of about 1 micron. The capillary loops after a course of some 0.5 mm converge to form the *efferent vessel*, which leaves the renal corpuscle close to the point of entrance of the afferent vessel. The diameter of the efferent vessel is only about one-half that of the afferent; its section

area is therefore only about one-quarter that of the latter.

The wall of the afferent vessel just before it enters the glomerulus loses its elastic membrane, the endothelium becomes discontinuous and the muscle fibers are overlaid and in part replaced by a cushion of myo-epithelioid cells (the *polkissen* of Zimmerman). We have seen (p. 377) that the distal tubule comes into contact with this part of the afferent vessel. The efferent vessel near its origin also contains discrete groups of myo-epithelioid elements. Cells possibly of a neural or secretory character are also found in the angle between the afferent and efferent arterioles. (The myo-epithelioid cells in the walls of the glomerular arterioles, together with those just mentioned in the angle between them constitute what has been termed the "juxta-glomerular apparatus." This structure, which also contains numerous nerve fibers has been thought by some to serve, an endocrine function, namely, the regulation of the glomerular blood flow by the liberation of renin (p. 132). Its hypertrophy in hypertension has been reported. The macula densa of the distal tubule (p. 377) probably should be considered functionally as an integral part of such a mechanism.

The distribution of the efferent vessel varies in accordance with the level in the kidney at which it arises;—(a) those which leave glomeruli situated in the outer part of the cortex break up into a network of capillaries which supply the proximal and distal convoluted tubules of this region. The efferent vessel from a given glomerulus as a rule supplies only the convoluted tubule of that nephron, i.e., there is little or no anastomosis between the circulations of neighboring convoluted tubules. (b) Those arising in the boundary zone between cortex and medulla soon divide into a leash of straight wide vessels—*arteriae rectae*—which run toward the kidney pelvis between the tubules of the medulla—Henle's loop and collecting tubules—around which they form a capillary network. (c) Those which combine the features of (a) and (b). These are found in the deep portions of the cortex. They first break up into branches for the supply of the convoluted tubules and then form straight vessels for distribution to the tubules of the medulla.¹

THE VENOUS RETURN. The blood having traversed the capillary vessels surrounding the convoluted tubules is collected into a venous plexus in the cortex. The blood from this plexus passes successively through interlobular, arcuate and interlobar veins which accompany the corresponding arteries. The interlobar

¹ Some of the afferent arterioles give off a communicating vessel (Ludwig's arteriole) which by-passes the glomerulus and connects with the capillary plexus surrounding the tubules. Occasionally an interlobular artery also gives off a branch which joins the capillary plexus directly. The number of these extra-glomerular vessels and consequently their functional importance is a matter of dispute. They increase in size in chronic kidney disease and then probably play a more important rôle than in health.

veins become confluent near the hilus of the kidney to form the renal vein. The capillary network derived from the *arteriae rectae* drain into *venae rectae* which in turn empty into the interlobular veins.

There are certain anatomical features of the renal circulation of special physiological interest which should be emphasized.

(1) Nearly all the blood which enters the kidney passes through the glomerular tufts.

(2) The tubules are therefore supplied largely by blood which has first passed through the glomeruli.

(3) The renal artery breaks up quite suddenly into short branches. This fact, to which attention was first drawn by Bowman, ensures that blood is delivered to the glomerular vessels under a high head of pressure. It should also be remembered that the renal artery is short, arises directly from the aorta, and is very large proportionately to the mass of tissue which it supplies.

(4) There is a striking disparity between the diameters of the *afferent* and *efferent* vessels.

The renal nerves

The kidney receives a sympathetic and a parasympathetic innervation.

(1) The SYMPATHETIC FIBERS arise from the sixth thoracic segment to the third lumbar inclusive. Functionally the fibers are of two types, *vasoconstrictor* and *afferent*. They are conveyed to the kidney in the *greater, lesser* and *least splanchnic nerves*. The greater and lesser splanchnic fibers synapse in the semilunar ganglion. The postganglionic fibers upon leaving the ganglion enter into the formation of the *renal plexus*, into which are also interlaced fibers of the vagus. From this plexus, which surrounds the renal vessels, non-medullated fibers may be traced to the arterioles, and to the glomerular and tubular capillaries. Nerve filaments have even been described between the cells of the tubules and of Bowman's capsule. The presence of ganglion cells within the substance of the kidney is a disputed question. The fibers of the least or lowest splanchnic nerve connect with cells within the renal ganglion situated in the hilus of the kidney; postganglionic fibers enter the renal substance.

(2) The PARASYMPATHETIC FIBERS are derived from the vagus. Their functions are unknown. The evidence is against either this nerve or the sympathetic supplying true secretory fibers to the renal cells. The effects upon urine formation caused by section or by the stimulation of any of the renal nerves are believed to be entirely the result of the vascular change which such section or stimulation has brought about. Carrel and Guthrie, and Quinby excised the kidney and transplanted it into another position. Though completely denervated by this procedure, the kidney excreted urine of the usual composition.

THEORIES OF RENAL FUNCTION

Bowman (1842) discovered the fundamental fact that the capsules surrounding the glomerular tufts are simply the expanded extremities of the renal tubules. Struck by the design of the glomerulus, which seemed to fit it so admirably to the purposes of a filter, he believed that this structure filtered water but that the solids of the urine were *secreted* by the cells of the tubules. Heidenhain maintained that the formation of urine was entirely a secretory process. Water and salts were the products of the glomerular membrane, while the more characteristic urinary constituents, urea, uric acid, etc., and under certain conditions water as well, were secreted by the tubular epithelium (see p. 386). He and his followers have endeav-

only be the same as those of plasma (less the proteins) but, if water alone underwent reabsorption, they should all be concentrated in the urine to precisely the same degree. We know that this is not so. Urea, for instance, is concentrated some 60 times, creatinine 70 times or more, whereas chloride may be concentrated only twice, and sugar appears in the urine in traces, if at all (see table 30). Either simple filtration must be deleted from Ludwig's theory and selective secretion substituted, or the conception of the reabsorption of water alone must be replaced by one postulating the re-absorption of water and certain solids in different relative proportions. Cushny's theory retains simple filtration by the glomerulus but postulates such a *selective re-absorption* by

TABLE 30

ored by almost countless experiments—largely involving the injection of dyes and the demonstration that these appeared in high concentration in the tubule cells—to prove the secretory function of the tubules. The theory of Ludwig was based upon purely physical conceptions. He believed that the glomerulus acted as a filter to remove from the plasma, water and all substances other than the proteins; and that the filtrate was concentrated in the tubular lumen through the return of the greater part of the water to the blood, by means of a simple process of diffusion.

Cushny's "Modern theory"

It is quite obvious that Ludwig's theory cannot be correct in its entirety; if filtration be granted, then the several urinary solids should not

the tubules. According to this theory the reabsorbed fluid is of constant composition under a conditions of health and resembles Locke's solution, i.e., one containing sodium, calcium, potassium, magnesium, chlorine and sugar, and in addition, small quantities of urea, uric acid, and phosphate. A selective process of this nature cannot be explained upon the basis of known physical laws, but entails "vital" activity, i.e. the performance of work by the tubular epithelium. Filtration, on the other hand, is "due to blind physical force." The glomerular membrane plays a passive rôle, performing no work (see table 30). These two processes, glomerular filtration and tubular re-absorption will now be considered in detail.

EVIDENCE FOR GLOMERULAR FILTRATION

(1) **STRUCTURE.** The peculiar features of the renal circulation—the great number of capillary loops in the glomerular tuft, the disparity between the calibres of its afferent and efferent vessels, the origin of the renal artery directly from the aorta, and its abrupt division into branches (p. 378) indicate that the development of pressure within the tuft is an important requirement for urine formation, and consequently strongly suggest that this part of the renal unit acts simply as a filter. On the other hand, a close examination of the glomerulus reveals nothing which might suggest its performing a secretory function.

(2) **THE FILTRATION PRESSURE.** [In order to drive fluid through a permeable membrane, there must be a higher pressure on one side. Variations in this pressure will alter the volume but not the composition of the filtrate. If urine formation involves filtration, alterations in the glomerular pressure should cause corresponding changes in urine volume. The glomerular pressure, however, depends not only upon the difference between the blood pressure within the capillary loops and the pressure in Bowman's capsule, but also upon the osmotic pressure of the colloids (proteins) of the plasma. This colloid pressure, which amounts to between 25 and 30 mm. Hg, opposes the pressure of the blood within the glomerular tuft. In other words, such an osmotic pressure requires that, in order for filtration to occur, the blood pressure shall be 25 or 30 mm. higher than it would need to be were the plasma protein-free.] The *effective* filtration pressure, or actual driving force, may be expressed thus—

$$P_b^{(75)} - P_o^{(30)} - P_c^{(5)} = P_f^{(40)}$$

Where P_b = blood pressure, P_o = osmotic pressure of proteins, P_c = pressure in Bowman's capsule and P_f = effective filtration pressure (see fig. 173).

Hayman measured the pressure in the afferent arterioles and the capillaries of the frog's kidney simultaneously with the aortic pressure. The method employed in measuring the pressure in the renal vessels was one based upon the general principle employed in human blood pressure estimations. A fine pipette was inserted into Bowman's capsule and the proximal convoluted tubule occluded by compression with a glass rod. Fluid was then run into the capsule under measured pressures. The pressure at which blood was observed to enter the vessels of the tuft, during systole only, was taken as the index of the systolic

pressure in the afferent vessel. As the pressure was gradually lowered below this level the flow in the capillaries became continuous. The pressure at which this occurred was taken to correspond to the pressure (diastolic) in the capillary loops. The following mean values were obtained.

Systolic pressure in aorta..	37.4 cm. H ₂ O
Systolic pressure in afferent vessel.....	31.6 cm. H ₂ O
Diastolic pressure in capillaries.....	20.2 cm. H ₂ O, or 54 per cent of the systolic aortic pressure

FIG. 173. Diagram illustrating the relation of blood pressure (P_b), osmotic pressure (P_o) and capsular pressure (P_c) upon the formation of urine. Aff. = afferent arteriole, Eff. = efferent arteriole.

Capillary pressures as high as 70 per cent of the aortic pressure were observed.

Numerous experiments of various types have been carried out to investigate the effects of one or other of the three factors mentioned above (P_b , P_o and P_c) upon the formation of urine. In general the results accord with a filtration process.

(a) *Blood pressure.* [Raising the general blood pressure causes a corresponding change in the urinary flow, provided that the agent which raises the systemic pressure does not cause a reverse change in the blood pressure within the kidney itself.] Stimulation of the splanchnic nerves, for example, with the renal nerves intact is likely to result in a reduction in urine volume from the kidney of that side, since its vessels share in the general vasoconstriction and the glomerular pressure is reduced. If the renal nerves are first cut, how-

ever, the general vasoconstriction and the renal vasodilatation (removal of constrictor tone) caused a higher pressure within the vessels of the kidney and a profuse flow of urine. Division of the cord in the thoracic region, by reducing the general blood pressure through the removal of vasoconstrictor tone, reduces the urinary flow. The fall in blood pressure following hemorrhage acts similarly.

(The rate of the renal blood flow as well as the pressure within the glomerulus, will be altered by the foregoing measures, and the altered blood flow, rather than the change in blood pressure, might be held responsible for the greater urine production. It was shown, however, by Richards and his associates that variations in glomerular pressure by itself caused parallel changes in urinary flow when special means were employed to

FIG. 174. Illustrating the effect of the intravenous injection of saline and of a gelatine-saline solution, respectively, upon the flow of urine. B.P. = blood pressure. The figures along the abscissa indicate the time in half-hours. (After Knowlton.)

keep the renal blood flow constant. It was also shown by these observers that in certain dosage adrenaline causes a relatively greater constriction of the efferent than of the afferent vessel. A rise in glomerular pressure and an increased flow of urine resulted.

(b) *Osmotic pressure of proteins.* As already stated, this amounts to between 25 and 30 mm. Hg. (The blood pressure in the capillaries of the tuft must therefore exceed the osmotic pressure in order that filtration shall occur (see also p. 43). The blood pressure in the capillary loop is around 60 per cent of the systolic aortic pressure, or from 70 to 80 mm. Hg. So then, over and above the sum of osmotic and intracapsular pressures, there exists a capillary pressure of from 35 to 50 mm. Hg which serves to drive fluid across the glomerular membrane. Reduction of the blood pressure by this amount (from 35 to 50 mm. Hg) suppresses urine formation.

The intravenous injection of isotonic salt solution causes profuse diuresis, resulting from, in part at least, the dilution of the plasma proteins; saline whose osmotic pressure has been raised by the addition of gelatin or gum acacia causes a diuresis only about one-third as great (fig. 174). Dilution of the plasma colloids permits the blood pressure to be reduced to a much lower level (under 20 mm.) before urine formation ceases. It is also well known that the urine volume is less in the standing position than in recumbency; this is due chiefly to the concentration of plasma protein which occurs in the former position (p. 20).

(c) *Intracapsular pressure.* Under ordinary circumstances this is low, probably not more than from 5 to 10 mm. Hg. It is largely due to the pressure of the surrounding renal substance (intrarenal pressure), for the kidney, it will be recalled, is enclosed in an inelastic fibrous capsule. When a manometer is tied into the ureter, the pressure in the tubules and capsule gradually rises. Urine formation ceases when the instrument registers a pressure equal to that by which the glomerular blood pressure exceeds the colloid osmotic pressure, i.e., when $P_o(30 \text{ mm.}) + P_c(45 \text{ mm.}) = P_b(75 \text{ mm.})$. Dilution of the proteins will permit the ureter pressure to be raised higher before urine formation ceases. The effect of raising the ureter pressure in suppressing urine formation is, of course, strong evidence for filtration; a true secretory process is not dependent upon a difference between the pressure in the vessels and that in the secretory ducts. The salivary gland, for example, continues to secrete though the duct pressure greatly exceeds the capillary blood pressure.

(3) *COMPOSITION OF THE CAPSULAR FLUID.* Wearn and Richards observed the glomeruli of the frog's kidney beneath the microscope and drew off fluid from Bowman's capsule by means of a fine pipette (fig. 175). The fluid had the composition of protein-free plasma. It was alkaline in reaction and contained urea, sodium chloride and glucose in practically the same concentrations as in plasma. Dyes injected into the animal appeared in the capsular fluid in the same concentration as in protein-free plasma. The molecular concentration and electrical conductivity of the capsular fluid and of de-proteinized plasma were also the same. The capsular fluid is therefore a filtrate. Walker and his associates have succeeded in recovering samples of fluid for analysis from the capsule and tubules of the mammalian kidney (guinea-pig and rat). The observations of Wearn and Richards upon the amphibian nephron have in general been confirmed.

(4) *THE PLASMA PROTEINS* when they pass into the urine do so in amounts which are inversely related to their molecular weights, showing that secretion plays no part, but that molecules escape through "pores" in the glomerular membrane. In kidney disease, serum albumin, which has a molecular weight of around 70,000, appears in the urine, as a rule, in greater amounts than does serum globulin (molecular weight

about 165,000).² Fibrinogen with a still larger molecule rarely escapes across the glomerular barrier. Hemoglobin, which has a molecular weight of a little over 68,000, when free in the plasma passes in the urine fairly rapidly,³ whereas hemocyanin, which has a huge molecule (mol. wt. 5,000,000) is not excreted. Inulins (mol. wt. 5200) and certain foreign proteins, such as egg white and gelatin with molecular weights around 35,000, and the abnormal Bence-Jones protein (p. 406) with a molecule of about the same size as the former two proteins are freely excreted. Edestin and casein, whose molecular weights are over 100,000, do not pass into the urine. The "pores" of the glomerular mem-

FIG. 175. Diagram showing Wearn and Richards method of obtaining a sample of fluid from Bowman's capsule. A fine glass rod (not shown in figure) is used to compress the proximal tubule just below the capsule and so to prevent fluid from being drawn from the tubule. When the glass bulb and tubing containing mercury is lowered, capsular fluid alone is withdrawn.

brane appear, therefore, to be of such a size as to allow the passage of molecules of a weight less than about

² Osmotic pressure determination.

³ Monke and Yuile estimate that only about 3 per cent of the "pores" of the glomerular membrane are sufficiently large to allow the passage of the hemoglobin molecule. It is possible, however, that the relatively free excretion of hemoglobin depends upon the fact that a proportion of the molecules are of smaller size than 68,000, that is, molecules with one, two or three atoms of iron, rather than that this small proportion of the "pores" are of such a size as to permit the passage of the largest molecules. These investigators find that part of the hemoglobin filtered through the glomerulus is reabsorbed from the tubules by phagocytosis.

70,000 (see Bayliss and associates and Bott and Richards). Hemoglobin and serum albumin are, therefore, near the border line, the former appearing in the urine only when its concentration in the plasma rises above 100 mgm. per 100 cc. Serum albumin may escape into the urine as a result, apparently, of even a slight change in the permeability of the glomerular membrane as in functional albuminuria (p. 405).

(5) OXYGEN CONSUMPTION. Certain measures, such as the injection of saline or the elevation of blood pressure, cause profuse diuresis but little or no increase in oxygen consumption (fig. 176). This is further evidence that physical processes are concerned, rather than secretion; the latter, of course, would entail oxidative processes and the expenditure of energy. Van Slyke and associates found that the oxygen consumption of the dog's kidney varied widely—from 0.04 to 0.30 cc.

FIG. 176. Graph of oxygen consumption by the kidney during diuresis following the intravenous injection of Ringer's solution and sodium sulphate. The black line represents the oxygen in c.c. taken up by each gram of kidney per minute. The shaded areas denote the volume of urine secreted each minute. Time in half-hours. A marked rise in oxygen consumption results from sodium sulphate but not from Ringer's solution. (After Barcroft and Straub.)

per gram of renal tissue per minute—but no relation between the oxygen consumption and the quantity of water or urea excreted was observed.⁴

It has been calculated that only about 1 per cent of the oxygen consumed by the kidney is used in providing energy for its excretory function (reabsorption). The remainder is used in non-excretory processes. It may also be mentioned incidentally here that the blood in the renal vein is usually more than 85 per cent saturated with oxygen, indicating that the oxygen tension is maintained at a higher level in the renal tissue than in most other tissues.

⁴ The experiments were made upon unanesthetized animals; one kidney was removed; the other, upon which the observations were made, was transplanted to a subcutaneous position.

The evidence in the foregoing paragraphs is conclusive for the view that the mammalian glomerulus acts as a filter.

THE EVIDENCE FOR TUBULAR REABSORPTION

Since glomerular filtration is an established fact, some measure, at least, of reabsorption by the tubules must be admitted. This is self-evident, inasmuch as bladder urine contains less water, no sugar and usually less chloride than the glomerular filtrate does. Wearn and Richards found chloride and glucose absent from frogs' urine, yet these substances were present in the capsular fluid. Also, the volume of the urine was only about $\frac{1}{10}$ to $\frac{1}{20}$ of the calculated volume of the filtrate. Water, chloride and sugar quite evidently were reabsorbed from the filtrate during its passage along the tubules. (Those substances, such as glucose, amino-acids, vitamin C, chlorine, sodium, potassium and calcium, which are absorbed with water to a relatively large extent and consequently are absent from the urine, or in low concentration, are called *high threshold substances*.) High threshold substances, however, appear in the urine in greater amounts if their concentrations in the plasma rise beyond a certain optimal threshold. The glycosuria in diabetes and the hypercalcuria of parathyroid excess (p. 708) are examples. *Low threshold substances* are those which are highly concentrated in the urine, since they are reabsorbed in relatively small amounts or not at all. *Urea, uric acid, phosphates and sulphates* are reabsorbed in variable amounts. *Creatinine* is concentrated to a greater extent than any other urinary constituent since it is not reabsorbed (see table 30). In certain pathological states of the kidney, creatinine may undergo passive reabsorption.

As further evidence for reabsorption the following experiments may be mentioned. Cushny found that when the ureter of one kidney was partially obstructed and the flow along the tubules thereby delayed, the urine from the obstructed side was more concentrated but contained less total chloride than that from the opposite kidney. These changes can be accounted for only by a greater reabsorption of salt and water. Diuretics, by increasing the flow, caused the production of a more dilute urine but increased the total urinary chloride and urea. The more rapid flow along the tubules reduces the time during which the absorption of water and reabsorbable solids can occur. Bieter and Hirschfelder injected dye into frogs and observed the kidneys by Richards'

method (p. 832). The glomerular fluid was stained within 20 minutes. Concentration (reabsorption of water) occurred progressively along the tubule, the color being deepest in the distal convoluted tubule. After the tubules have been poisoned by mercury or cyanide, concentration does not occur. Poisoning of the tubule, however, though it abolishes the specific reabsorptive process permits water and other substances to pass back into the blood by a simple process of diffusion (see passive reabsorption). This latter process has been clearly demonstrated by Richards, who found that complete suppression of urine formation (anuria) may follow the administration of a tubular poison though filtration continues at the normal rate.

(The proximal tubule is responsible for the reabsorption of sugar, phosphate, sodium and part of the chloride, and for about 65 per cent of the water of the filtrate. The filtrate remains isotonic with the plasma in the proximal tubule. The remainder of the reabsorbed water and chloride is taken up by the distal part of the nephron. Here the filtrate becomes hypotonic and is acidified as a result of reabsorption of base.) Hemoglobin, when injected into the circulation, is deposited as the insoluble acid hematin when acted upon by the acid urine; this has been observed to take place in the distal tubule of the frog's kidney.⁴⁰

(In its transfer across the tubular membrane, phosphorylation of the glucose⁴¹ molecule appears to be a necessary preliminary step. The change is brought about by a specific enzyme, *kidney phosphorylase*. Dephosphorylation of the hexose phosphate thus formed is effected by a second enzyme, "*alkaline*" *phosphatase*, present in the cells of the proximal convoluted tubules.)

(The absorption of sodium from the proximal tubule is influenced by the adrenal cortex and the

⁴⁰ This fact has a practical bearing when large amounts of hemoglobin are liberated, as may occur after the transfusion of incompatible blood (p. 35).

⁴¹ Phloridzin acts selectively upon the proximal tubule preventing the reabsorption of glucose and the secretion of creatinine. The first of these effects is the cause of the "diabetes" following the administration of the drug. Phloridzin exerts this action most probably by inhibiting phosphorylase (Kalcar; Kritzler and Gutman), but has no effect upon the "*alkaline*" *phosphatase*. Lundsgaard suggested that phloridzin inhibited phosphorylation and dephosphorylation by *phosphatase*, but several observations have since been recorded which are opposed to this idea. Hudson and Walker, for example, found that iodoacetate which prevents the esterification of glucose by *phosphatase* did not cause glycosuria, nor is the *phosphatase* activity of the kidney abolished by phloridzin.

principle of the posterior pituitary gland. The hormone of the adrenal cortex is essential for the normal reabsorption of sodium; in adrenal insufficiency increased excretion of this element is, therefore an outstanding feature. The effect of corticosterone and of desoxycorticosterone is even more pronounced than that of cortin. The antidiuretic hormone of the pituitary, inhibits the reabsorption of sodium and chloride and increases the reabsorption of water.) According to Shannon, the (pituitary hormone acts upon the distal tubule in respect to the reabsorption of water and inhibits the reabsorption of sodium though an action upon the proximal part of the nephron. There is evidence that the parathyroid hormone lowers the renal threshold for phosphate. Thyroxine appears to antagonize the antidiuretic action of the pituitary hormone.)

Experimental evidence points to the cells of the distal part of the nephron as the site of the formation of ammonia and hippuric acid.

Smith and his associates find by means of the inulin clearance method (p. 404) that the quantity of filtrate formed by the human kidney is around 125 cc. per minute. At this rate nearly 200 liters of fluid would be filtered in 24 hours. Of this, about 99 per cent is reabsorbed by the tubules.

CRITICISMS AND MODIFICATIONS OF CUSHNY'S THEORY

In its broad outlines the filtration-reabsorption conception of renal function is firmly established on a sound experimental and clinical basis. Certain of its details however require revision in the light of certain experimental and clinical observations. The main modifications in Cushny's theory which more recent work has made necessary are concerned with the contention that the reabsorbed fluid is constant in its composition and the denial of tubular excretion. These questions will now be considered.

Constancy in composition of the fluid removed from the filtrate by reabsorption implies that under changing conditions of urinary flow the concentrations of the several low threshold substances should also remain constant, relatively to one another. Let it be supposed, for example, that 100 cc. of filtrate contains 20 mg. of urea and 1 mg. of creatinine and, after the reabsorption of water (together with sugar, salts and urea), 100 cc. of urine contain 1000 mg. of urea and 75 mg. of creatinine. The concentration ratio of urea ($\frac{\text{mg. urea in 100 cc. urine}}{\text{mg. urea in 100 cc. plasma}}$), therefore, is 50 and

that of creatinine 75. A reduction in the quantity of filtrate and, therefore, in the flow along the tubules will cause more fluid to be reabsorbed; if the composition of the reabsorbed fluid remained the same, parallel rises in the concentration ratios of urea and creatinine should occur. Such a relationship, however, does not hold, either in health or in disease. In brief, creatinine is not reabsorbed⁶ whether the urine flow is slow or rapid whereas the quantity of urea excreted in the urine varies, more being returned to the blood in the reabsorbed fluid with slow than with rapid rates of urine flow. The same is true of other constituents (e.g., uric acid and phosphates) of the glomerular filtrate.

(The constituents of the glomerular filtrate are grouped by Rehberg into three classes according to the manner in which they behave towards the reabsorption process: (a) Substances which are *actively reabsorbed*, namely, those already referred to on page 384 as high threshold substances (glucose, Na, K, Ca, Mg and Cl). These substances are conserved to the body and are usually in lower concentration in the urine and in higher concentration in the reabsorbed fluid than in the plasma. (b) Substances which pass back through the tubular epithelium by a simple process of *diffusion* when their concentrations in the tubular fluid rises above their concentrations in the plasma. These are the substances already referred to as low threshold substances, namely, urea, uric acid, endogenous sulphate and phosphates. They are *passively*, never actively, reabsorbed. It has been estimated that in health from 40 to 50 per cent of the filtered urea is returned in this way to the blood. These materials are never in lower concentration in the urine nor in higher concentration in the reabsorbed fluid than in the plasma. (c) *Non-threshold substances*, which suffer neither active reabsorption nor back diffusion. They are therefore absent from the reabsorbed fluid.

Rapid flow of urine along the tubules will reduce active reabsorption as well as back diffusion, but not both processes to the same extent. It is obvious that the more a substance undergoes active reabsorption or back diffusion, the less of it will appear in the urine. Back diffusion of low threshold substances and also apparently of a high threshold substance, such as chloride, is encouraged by a rise in their concentrations in the filtrate.) Experiments by Rehberg upon chloride

⁶ In kidney disease a considerable quantity of creatinine may be reabsorbed as a result of simple diffusion.

elimination showed that only when the chloride of the plasma was below 375 mg. chlorine per 100 cc. did the chloride concentration of the reabsorbed fluid⁷ exceed that of the plasma and of the urine (i.e., undergo active reabsorption). When the chloride concentration in the plasma was high (above 375 mg. chlorine per 100 cc.) its concentration in the reabsorbed fluid was always below that of the plasma and the quantity excreted in the urine was raised; in short, it was treated as a low threshold substance, passing into the reabsorbed fluid by back diffusion alone. Other high threshold substances probably behave in a similar way.

The question of excretion by the tubular epithelium

From Heidenhain's time to the present innumerable experiments have been performed in attempts to prove or disprove the secretory hypothesis. Only a few of the more important and more recent experimental results can be given.

(a) Marshall and Vickers found that injected phenol-red appeared in the plasma in two forms, of which one was *protein-bound* (unfilterable) and the other *free* (filterable). Following injection more dye appeared in the urine than the quantity of blood which was calculated to have passed through the kidney during the experiment could have contained in filterable form. Part of the dye, it was argued, must therefore have been excreted by the tubules. Also, when the blood pressure was reduced to the point where glomerular filtration ceased and the dye then injected, the kidney contained a higher concentration of dye than the serum or other tissues. Microscopical examination showed deposition of the dye in the cells of the convoluted tubules; it was absent from the lumen. The dye therefore entered the cells from the blood and not simply by re-absorption from the tubules. Sheehan has carried out cognate experiments and arrived at a similar conclusion concerning tubular function.

(b) Chambers and his associates have demonstrated the excretion of phenol red by the mesonephric tubule of the embryonic chick and by the metanephric tubule of a 3½ months human embryo. Employing a micro-manipulative technique the tubules were broken up into sections. Within the first few hours or so of incubation the open ends of the fragmented tubules close and their lumina then become distended with fluid transferred from the surrounding culture medium.

⁷ The reader is referred to Rehberg's papers for the details of the method for determining the composition of the reabsorbed fluid. Rehberg determined the filtration rate in human subjects from the creatinine clearance, believing that the substance was neither excreted nor reabsorbed. This has been shown to be erroneous; his filtration values were therefore too high. His general conclusions are, nevertheless, essentially correct.

Phenol red added to the culture medium was taken up by the tubular cells and concentrated within the cyst-like structures. Cooling the culture to 30°C. CO₂, H₂S or lack of O₂ stops the process, the tubular epithelium being then permeable in both directions to water and dye.

(c) Evidence for the tubular excretion of creatinine in man has been obtained by comparing its clearance with that of inulin (p. 404). Inulin is neither reabsorbed nor excreted by the tubules. Its clearance, which is therefore a measure of glomerular filtration is considerably lower than that of ingested creatinine. The latter must therefore be excreted by the tubules.

(d) The kidneys of certain fish (e.g. toad-fish) possess no glomeruli. Each nephron consists of a segment analogous to the proximal convoluted tubule of mammals. Nevertheless, urea, creatinine, phenol-red and such iodine compounds as diodrast and hippuran, when injected appear in relatively large amounts in the urine. Also, as shown by Marshall, the glomerular function of the sculpin can be abolished by phloridzin. The functionally aglomerular kidney nevertheless, excretes urea, uric acid and injected dyes.

Tubular excretion (of uric acid) is also a prominent feature of renal function in birds and reptiles.

The question of tubular excretion may be summed up by saying that, though dyes, creatinine,⁸ diodrast etc., are excreted by the proximal tubules of the mammalian kidney, such a process is probably of relatively little importance under ordinary circumstances and may be no more than a functional relic inherited from primitive forms. It seems unnecessary to invoke tubular excretion⁹ to explain the several phases of renal activity. Nor does such a conception aid greatly in the interpretation of renal disease. Glomerular damage and reduction in filtration go hand in hand with the ability of the kidney to clear the blood of urea (p. 403). Also, in acute nephritis the glomeruli are chiefly involved in the inflammatory process, filtration is reduced and retention of urea in the blood may be a pronounced feature; in lipid nephrosis (p. 400), on the other hand, there is little or no detectable injury to the glomeruli whereas the tubule cells show striking degenerative changes, filtration is apparently unimpaired and urea retention (which one should expect were the excretion of this substance an important duty of the tubules) does not occur. On the other hand

⁸ Creatinine is excreted by the human kidney but not by the dog's kidney.

⁹ Statements regarding tubular excretion are not intended to refer to such substances as ammonia and hippuric acid which are formed by the kidney and passed into the urine. Excretion of these substances is an important renal function (p. 391).

it is quite possible if not probable that in chronic kidney disease involving the glomeruli (glomerulonephritis) the primitive excretory functions of the tubules may be called upon to play a much more important rôle than they do in health.

THE REGULATION OF THE URINARY FLOW

(The volume of the urine may be increased by (1) increased rate of filtration, (2) reduced rate of reabsorption, or (3) by a combination of both. Reduction in urinary volume results from corresponding changes in a reverse direction. It should be remembered that a relatively slight percentile alteration in (1) or (2) will cause a relatively great change in the urine volume. If, for instance, the quantity of the reabsorbed fluid remains constant but filtration is increased by only 1 per cent, say, from 100 to 101 liters in twenty-four hours, the urine flow (taking 1500 cc. as the average daily excretion) will be increased by over 60 per cent. A reduction of 1 per cent in the quantity of reabsorbed fluid (filtration remaining constant) will increase the urine volume to a comparable extent.

(1) **FACTORS WHICH INFLUENCE THE FILTRATION RATE.** (a) Variations in the size of the filtering surface. Richards and Schmidt showed that the number of patent glomeruli in the kidneys of frogs varied from time to time under various nervous and chemical influences (fig. 177). Nor is the number of open capillaries in an active glomerulus fixed. At one moment, under a certain condition, only a few loops may be patent, at another moment, under changed conditions, the glomerulus appears as a red ball with all its vessels dilated (Ekehorn). The intermittence of function demonstrated for the amphibian glomerulus probably does not apply to the mammalian kidney. The evidence indicates that in the rabbit, the dog and the human subject the glomeruli are continuously active (White; Shannon; Smith and associates).

(b) Changes in pressure within the capillary loops. Such may result from alterations in caliber of the afferent or efferent vessels (dilatation of the former or constriction of the latter will increase the glomerular pressure), or from changes in the systemic blood pressure. A rise in general arterial pressure, apart from any vascular changes within the kidney itself, will increase both renal blood flow and glomerular pressure. According to Erlanger and Hooker the magnitude of the pulse pressure is also an important factor in renal activity (see also p. 132).

(c) Changes in the renal blood flow. The extent to which a rise in glomerular pressure alone can augment filtration is limited by the fact that as fluid is expressed from the capillary loops the contents of the latter undergo a considerable reduction in bulk. As a consequence, the intra-capillary pressure tends to fall and the osmotic pressure to rise. These effects will, of course, slow the filtration rate. It has been estimated that under ordinary circumstances from about 20 to 25 per cent of the plasma is filtered from the blood in its passage through the glomerulus. The blood within the capillary must therefore undergo renewal at a certain rate in order to maintain filtration at a high level.

FIG. 177. Variations in capillary pathway within a single glomerulus. *a*, 5 minutes before an intravenous injection of 0.1 cc. of 10 per cent glucose: blood flow very slow. *b*, 10 minutes after glucose: blood flow still slow. *c* and *d*, 25 and 30 minutes after glucose: blood flow more rapid and cells less closely packed. *e*, 45 minutes after glucose: blood flow slow, cells densely packed: *f*, 9 minutes after intravenous injection of 0.5 cc. 0.7 per cent NaCl: flow more rapid and cells less dense. *g*, immediately after injection of 0.1 cc. adrenaline 1/100,000 blood flow very slow. *h*, 5 minutes after *g*: blood flow rapid. (After Richards and Schmidt.)

The blood flow through the human kidneys under various conditions has been measured by Smith and his associates by means of the diodrast plasma clearance method and obtained a value of around 1300 cc. per minute (both kidneys) or more than a quarter of the cardiac output. Diodrast, an iodine compound, when in low concentration in the plasma undergoes complete clearance, i.e., it is completely removed from the plasma in a single passage of the blood through the kidney. This substance is excreted largely by the tubules, only a small fraction (approximately 16 per cent) being filtered through the glomerulus. Knowing the amount excreted in the urine within a unit of time and the concentration in the plasma, it is a simple matter to calculate the quantity of blood which has passed through active renal tissue. By way of illustration let us take some representative figures. Say that 700 milligrams of dio-

drast are excreted in the urine each minute and each cubic centimeter of plasma contains 1 mgm.; obviously then in the delivery of the 700 mgm. of diodrast 700 cc. of plasma, or about 1300 cc. of blood, must have passed per minute through the kidneys.¹⁰ The human kidneys together weigh about 300 grams, a blood flow of 1300 cc. per minute therefore amounts to over 4 cc. per gram of renal tissue per minute. This figure is in close agreement with that obtained by direct determinations of renal blood flow made upon laboratory animals, the minute flow for the rabbit being given as between 4 and 7 cc. per gram of tissue.¹¹ If the filtration rate as well as the plasma flow is known, the percentage of the plasma filtered from the blood can be readily calculated. Thus the filtration rate, as determined by the inulin method, is around 125 cc. per minute, therefore the plasma in passing through the glomerular capillaries loses about $(\frac{125}{700} \times 100 =)$ 18 per cent of its bulk. This figure is not constant but, as indicated above, is altered by several conditions, e.g., the pressure within the glomerular capillaries, the rate of blood flow through them, etc.

Some of the more interesting physiological features of the blood supply to the kidney may be mentioned here. The renal circulation possesses a greater degree of independence in respect to the general circulation than most other vascular areas. There is little definite information concerning the basis of this autonomy, though the juxta-glomerular apparatus (p. 379) is suspected of playing a dominant rôle; the controlling mechanism is not impaired by denervation of the kidney. The renal vessels do not share in the reflex vasoconstriction which follows hemorrhage nor in other reflexes initiated from the carotid sinus or aortic arch. Reactive hyperemia (p. 271) which is readily induced in other vascular areas, e.g., skin

and cardiac muscle, is not shown by the renal circulation, nor is denervation of the kidney followed by augmentation of the blood flow. Certain fever-producing agents (pyrogens), such as typhoid vaccine, however, cause a pronounced increase in renal blood flow.

(d) *Changes in protein content* and so in the osmotic pressure of the plasma (p. 381).

(e) *Changes in the rate of reabsorption.* In the absence of any other means of facilitating the progress of the filtered fluid through the long and narrow tubules to the renal pelvis, a high pressure within Bowman's capsule would be required (80 mm. Hg, according to Brodie). There would then be the need for a glomerular blood pressure sufficient not only for filtration but for the creation of this high intracapsular pressure in order to overcome the resistance in the urinary channels. Reabsorption renders such a pressure unnecessary. In the first place a certain proportion of the fluid need be driven only as far as the proximal convoluted tubule where the reabsorption process commences (p. 384). The passage of the remainder of the filtrate beyond this to the distal convoluted tubule is facilitated by the withdrawal by reabsorption of the layer of fluid in immediate contact with the wall of the tubule. In the passage of fluid along an ordinary capillary tube the layer of fluid in contact with the wall of the tube is stationary; friction develops between this and the next layer and between successive layers toward the axis of the stream. As a result of the reabsorption process frictional resistance is reduced to a minimum. When, on the other hand, tubular function is impaired the development of a high intracapsular pressure is required in order to overcome the increased resistance and drive fluid along the tubule. Filtration is materially reduced in consequence.

(2) THE REGULATION OF REABSORPTION. The chief factors are: (a) the rate of flow along the tubules; the faster the flow, the shorter is the time permitted for reabsorption to occur. (b) When sufficient time is allowed, the osmotic pressure of the fluid in the tubules is the factor which brings reabsorption to an end. As a result of the reabsorption from the filtrate of a more dilute fluid than the filtrate itself, concentration of non-threshold substances in the tubular fluid and a rise in its osmotic pressure must occur. Reabsorption ceases when the epithelial cells are incapable of performing the work necessary to overcome the osmotic resistance. Back diffusion of low threshold substances tends to increase, how-

¹⁰ In order for a substance to serve as a means of measuring the plasma flow it must not be stored by the kidney nor taken up by the blood cells. All the evidence indicates that in the human subject, at least, these requirements are for all practical purposes fulfilled by diodrast.

¹¹ Van Slyke and associates obtained values in unanesthetized dogs of from 2 to 10 cc. per gram per minute. The bloodflow was calculated from the urea N excretion per minute in milligrams (E) and the difference between the urea contents of renal arterial (A) and renal venous (R) bloods in milligrams per cubic centimeter. Thus,—

$$F = \frac{E}{A - R}$$

where F = blood flow in cubic centimeter per minute.

ever, as the concentration rises. The concentration of the solute in the interstitial fluids, i.e., the fluids on the other side of the tubular membrane, is a factor of equal importance. As this concentration approaches that of the tubular fluid, reabsorption becomes progressively lower and ultimately ceases.

In the reabsorption of a substance from the filtrate there is a maximum rate which may be expressed in milligrams per minute and is conveniently designated by the symbol *T_m*. (maximum transfer). Thus the maximal rate of reabsorption of glucose, or *glucose T_m*, amounts to about 320 mgm. per minute in man. It is determined by raising the plasma glucose concentration and measuring simultaneously the rate of filtration (inulin clearance method, p. 404) and the excretion of sugar in the urine. When the filtration rate of glucose rises above the maximum rate or reabsorption, glycosuria occurs.

The reabsorption process is not subject to direct nervous influences, nor, of course, is the purely passive process of filtration. The effects upon renal function exerted by the nervous system are the result of its action upon the circulation and, possibly, upon the activity of certain ductless glands. In the latter connection the results of Theobald and Verney may be cited. These observers found that afferent nerve stimulation caused inhibition of water diuresis of the completely denervated kidney. They suggest that the antidiuretic effect is brought about through pituitary secretion (p. 390). The pituitary hormone exerts its antidiuretic effect most probably by increasing reabsorption.

DIURESIS

Substances such as *caffeine*, *sodium sulphate*, *urea*, *mercurial salts*, *acidifying salts*, e.g., CaCl_2 , NH_4Cl , and under certain circumstances *digitalis*, act as powerful *diuretics*. *Caffeine* appears to exert its action in part at least by causing renal vasodilatation. *Caffeine* increases the chloride concentration of the urine, and lowers the concentration of urea; but the absolute amount of the latter substance excreted is increased (Verney and Winton). The action of *sodium sulphate* is ascribed by Cushny chiefly to reduced re-absorption. Since the epithelial cells are relatively impermeable to sulphate, it increases the osmotic pressure of the fluid within the lumen of the tubules; the work demanded for the reabsorption of the usual quantity of fluid exceeds the capacity of the tubular epithelium. According to Eadie and his associates sulphate also increases the renal blood flow and the filtration rate. *Urea*, and the *ammonium salts* which

are reconstituted in the body into urea, act as diuretics in a similar manner. Urea may also increase the filtering surface, more glomeruli becoming active. The *polyuria* of diabetes is due to the high concentration of sugar in the glomerular filtrate; as in the case of sulphate diuresis the osmotic pressure level at which re-absorption ceases is reached sooner than under normal circumstances. The polyuria and glycosuria following the administration of *phloridzin* is due to the paralysis of tubular function. The action of this drug is mainly upon the proximal tubules. *Salysrgan*, a mercurial diuretic, probably acts also by depressing re-absorption. *Digitalis* has practically no diuretic action in a healthy person nor in a patient suffering from cardiac failure but with no edema. On cardiac edema, but not on other types, the effect is striking, marked diuresis occurs and the edema is reduced. The result is undoubtedly due to the specific action of the drug upon the failing circulation. *Alcohol* is a powerful diuretic; the diuresis resembles water diuresis; it is antagonized by pituitrin.

Water and saline diuresis

The ingestion of large quantities of water by a normal person causes the urine output to increase many-fold. The extra water is eliminated within 4 hours or so, and the greater part of it within 2 hours. The diuresis does not commence until from 30 to 60 minutes after the water has been drunk. Normal or hypertonic saline given by mouth, on the contrary, causes relatively little effect upon the urinary flow. Normal or hypertonic saline or water given intravenously causes profuse diuresis (p. 382). The diuretic effect of the oral or intravenous administration of water is much less in anesthetized than in conscious animals. Water diuresis is also inhibited (as a result apparently of the release of the pituitary antidiuretic substance) by muscular exercise, by afferent nerve stimulation (Theobald and Verney) and in certain emotional states.

The urine after water drinking is very dilute, the specific gravity ranging between 1.000 and 1.002, i.e., considerably lower than that of the plasma; the percentage of chloride as well as the total quantity excreted is greatly reduced. The urea percentage is also reduced, though the absolute quantity excreted may be doubled.

The processes involved in the diuresis following the ingestion of water are complex and not fully understood; the phenomenon has been the subject of numerous investigations. In the experiments of Priestley, from 2 to 3 liters of water were drunk within a few minutes. The diuresis was accompanied by an increase of only about 2

per cent in the water of the blood, and this is quite inadequate to explain the large quantity of urine excreted on the basis of dilution of the plasma proteins. Nor could a rise of 2 per cent in the total blood water account for more than a small fraction of the water ingested. Furthermore, the blood dilution actually passes its maximum and is declining again before the diuresis commences. In these experiments, the results of which have been confirmed in general by others, the blood chloride fell by 5 per cent and the electrical conductivity of the plasma to a corresponding extent; obviously such a reduction in chloride could be only partly accounted for by the blood dilution, and the fall in urinary chloride is evidence that the salt does not escape through the kidney. It appears that the great bulk of the ingested fluid leaves the vessels and is followed, or accompanied by salt which serves to preserve the isotonicity of the tissue fluids. Such a migration of salt would account to a large extent for the fall in blood chloride. The load of fluid is subsequently discharged from the tissues in a slow but steady stream and transported to the kidneys.

The delayed onset of the diuresis following the ingestion of water is not due simply to the time required for absorption from the intestine, for a similar delay occurs when the diuresis is caused by the intravenous administration of water.

Inhibition of tubular reabsorption is an important factor in water diuresis; chloride, on the contrary, appears to be reabsorbed more completely. Such urine with its low chloride content resembles that formed by the isolated kidney (i.e., one freed from pituitary control (p. 397)). The diuresis following lesions in the region of the pituitary (p. 739) also resembles the diuresis of water drinking, and the latter, like the former, can be inhibited for several hours by the administration of pituitrin or of acetylcholine which is believed to cause the liberation of the pituitary antidiuretic principle. The chloride content of the urine during the period of inhibition is around the normal level. Pituitary removal in animals increases the output of urine (less water reabsorbed) and increases the absorption of chloride. It has been mentioned, page 389, that afferent nerve stimulation inhibits water diuresis of a denervated kidney. The inhibitory effect must therefore be brought about through the blood stream; Theobald and Verney secured evidence which suggests that the liberation of the antidiuretic principle from the pituitary is the responsible factor.

The foregoing observations suggest that the pituitary hormone is concerned in water diuresis and that it influences the re-absorption of water and salt by the tubule cells. But it is not at present possible to arrive

at any definite conclusion as to the precise manner in which it acts. Suppression of the antidiuretic principle of the pituitary brought about in some way by the passage of the ingested fluid into the tissues, either through the liberation of a tissue hormone or by afferent nerve impulses, is a distinct possibility. Several observations suggest that the pituitary effect is brought about through the nervous system rather than through some change in blood composition acting directly upon the gland. A conditioned diuretic response, for example, can be established in animals, and diuresis can be induced by suggestion in patients during hypnosis; the inhibitory effect exerted by anesthetics, narcotics or emotional states upon water diuresis has been mentioned. Verney and his associates favor this conception, namely, that the diuretic response is the result of the suppression of the secretion of the antidiuretic principle of the pituitary through nerve impulses. The antidiuretic effect will not, of course, be abolished immediately upon the suppression of the pituitary secretion; a certain time will elapse before the quantity of the pituitary principle already present in the circulation is removed. This would account for the delay in onset of the diuresis after the water has been absorbed. As the concentration of circulating hormone becomes reduced the kidney, released from the restraining influence, increases its output. The pituitary reasserts its antidiuretic influence again after the load of tissue fluid has been removed. On the other hand, the experiments of Smirk and Newton indicate that the pituitary is not absolutely indispensable for the production of water diuresis. They claim to have obtained the typical response in animals after removal of the pituitary, hypothalamus and all brain tissue above the tentorium cerebelli.

Smirk and associates have also carried out a number of instructive experiments upon water diuresis in man and animals. By means of an ingenious procedure they were able to weigh separately the abdomen and limbs of a human subject or of an intact animal after water drinking. They took the progressive reduction in weight of the abdomen and the increase in weight of the limbs as indices of water absorption from the intestinal tract and water deposition in the tissues, respectively. The weight of the abdomen was found to increase immediately after the water was drunk; it then gradually declined for a period of from 22 to 55 minutes while the leg weight increased. After drinking 1 liter of water the leg weight increased by 1.5 per cent (1 liter was 1.3 per cent of the subject's body weight). This figure agrees closely with one calculated upon the basis that the absorbed water was distributed generally throughout the tissues of the body. The leg weight gradually declined during the diuresis. The decline was delayed by pituitrin. Absorption was found to be complete and the dilution of the blood was falling from its maximum before the diuresis commenced. These observers conclude therefore that the diuresis is not simply the result of the blood dilution but that renal activity was

initiated in some other way after practically all the absorbed water had entered the tissues.

REDUCTION IN THE URINARY FLOW

The urinary flow is reduced in muscular exercise, presumably a result of the diversion of blood to the active muscles; in cardiac failure, as a result of the engorgement of the renal vessels and slowing of the blood flow (p. 148); in acute inflammatory conditions of the kidney; in the later stages of chronic nephritis; in fevers and in dehydrated states, or when the fluid intake is reduced. The effect of pituitrin upon the urine volume has been mentioned (see also p. 731).

THE PRODUCTION OF AMMONIA BY THE KIDNEY—HIPPURIC ACID FORMATION

The experiments of Nash and Benedict in 1921 furnished evidence for the renal origin of urinary ammonia. (1) The blood of the renal vein contains 2 or 3 times more ammonia than does the blood of the renal artery. (2) The ammonia of the systemic blood is not altered by conditions which increase the ammonia of the urine (p. 392). (3) In animals the blood ammonia does not rise after bilateral nephrectomy nor in nephritis though the urinary ammonia is often reduced. (4) In diabetic acidosis the blood ammonia is not greater than normal, yet the urinary ammonia is greatly increased.

Urinary ammonia has been thought to be derived mainly from urea and to a less extent from the deaminations of amino acids. However, Van Slyke and his colleagues have shown that glutamine is the chief source. Amino acids furnish a smaller proportion, but none is derived from urea. They found that all the urea removed from the blood by the kidney was excreted unchanged, whereas the glutamine so removed accounted for at least 60 per cent of the urinary ammonia.

The kidney (as well as the liver) conjugates glycocholic and benzoic acid with the production of hippuric acid (benzoyl-glycine). This is a detoxicating process.

THE REACTION OF THE URINE AND THE RÔLE PLAYED BY THE KIDNEY IN THE REGULATION OF THE ACID-BASE BALANCE

The acidity of the urine may be expressed in two ways, either with regard to (a) *its concentration in hydrogen ions*, i.e., its true acidity, or (b) the total quantity of free acid present as determined by titration with N/10 sodium hydroxide

using neutral red or phenolphthalein as indicator. This measurement, which is expressed as the number of cubic centimeters of N/10 alkali used for the titration, is called the *titratable acidity*.

(a) THE pH OF NORMAL URINE usually lies between 5.0 and 7.0 with a mean of 6.0. The extremes in health are 4.7 and 8.0. The pH of urine is determined mainly by the proportions of the di-basic (alkaline) and mono-basic (acid) phosphates which it contains. The kidney receives blood at a pH of about 7.40 and forms urine with a pH of around 6.0. It accomplishes this by altering the proportions of the acid and alkaline phosphates. The ratio of these in the plasma is $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{1}{4}$ whereas in urine with a pH of 6

the ratio is more than reversed, being $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{9}{1}$.

When the urine is at its greatest acidity the ratio is 50:1. By this device a large amount of the body's fixed base (Na chiefly, but also K, Mg and Ca) is conserved. The change from di-basic to the mono-basic salt probably takes place during the passage of the urine through the distal tubule. Wearn and Richards found that the glomerular filtrate of frogs was alkaline in reaction whereas the urine was acid. Cushny found that in dogs the injection of di-sodium (alkaline) phosphate increased the acidity of the urine. A portion of the sodium of the injected salt was retained and the resulting acid phosphate was excreted. It was also found that when the di-basic salt was injected into an animal with one ureter partially obstructed (to increase absorption from the tubules) the urine from that side was more acid than was the urine coming from the free ureter. The injection of such substances as sodium chloride or sodium sulphate was found to reduce the acidity of the urine since they caused diuresis, the rapid flow of urine through the tubules curtailing the conversion of di-basic phosphate to the mono-basic salt. The chemical change which probably occurs in the tubules is shown below:

The bicarbonate is reabsorbed by the epithelium of the tubules.

In alkaline urines the pH is determined chiefly by the carbonic acid—bicarbonate ratio $\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3}$ (see below). The pH and volume of the urine in health and under usual conditions vary together

and in the same direction; a urine of a small volume being usually of a lower pH than one of larger volume. A urine of average acidity (pH 6.0) may have its pH raised to 7.0 by maximum diuresis but rarely higher than this.

(b) **TITRABLE OR TOTAL ACIDITY.** By this is meant the quantity of acid in excess of basic substances (i.e., the free acid) present in the urine. The greater part of the titratable acid is phosphoric in the form of the mono-basic (chiefly sodium) salt. A small part of the titratable acid is due, however, to free organic acids, uric, lactic, hippuric, etc. The usual amount of titratable acid in a 24-hour specimen of urine lies between 200 and 400 cc. of N/10 standard acid. Its amount, however, depends in health upon several conditions and may be as low as 100 cc. or as great as 600 cc. In severe diabetes it may be 2 or 3 times the latter figure, as a result of the excretion of large quantities of acetoacetic and β -hydroxybutyric acids (acetone bodies).

The total acidity is determined by titrating the urine with N/10 sodium or potassium hydroxide, the result being expressed as the number of cc. of N/10 alkali required to bring 100 cc. of urine to near the neutral point, the precise reaction attained depending upon the indicator used. When the titration is carried out to the pH of blood (7.4) the result obtained has a greater physiological significance than if the urine were exactly neutralized (pH 7.0). In Henderson and Palmer's method neutral red, which turns a brownish red at the normal blood reaction, is used as indicator. When the urine is titrated to the reaction of the blood, the procedure obviously reverses the change in reaction which the kidney had effected during the formation of the urine from plasma. The quantity of alkali added is therefore a measure of the quantity of fixed base which the kidney has saved to the body by the conversion (chiefly) of the di-sodium phosphate to the corresponding acid salt. Frequently, phenolphthalein is used as the indicator in titrations of urinary acidity (Folin's method) but since this indicator turns color (colorless to pink) at a pH of 8.2, it is clear that the result will be considerably higher than when neutral red is employed, and urine which is actually neutral or alkaline, or even blood plasma itself will then have a titratable "acidity."

BASE-CONSERVATION BY THE KIDNEY

The stores of base in the body fluids can be replenished only from without. The kidney plays an important rôle in preventing the depletion of these stores. One important method of conservation, namely, the conversion of the di-basic to the mono-basic phosphate, has just been mentioned. For every molecule of alkaline phosphate converted in the tubules of the kidney to the acid salt one molecule of NaHCO_3 is returned to

the body's store of alkali. Or, put in another way, about 40 per cent of the base bound to phosphoric acid in the plasma is saved by the conversion of the di-basic phosphate to the mono-basic form.¹²

Another means of conserving base is the retention of part of the base combined in the blood with organic acids and the excretion of the latter in the free state; this though of little importance in health is of great importance in disease. Organic acids may pass into the urine in three ways: (a) in combination with fixed base (urates, hippurates, lactates, etc.), (b) in combination with ammonia, or (c) free. In highly acid urines according to Henderson and Palmer uric acid is 91 per cent free, lactic 12 per cent and hippuric 8 per cent. The abnormal organic acids acetoacetic and β -hydroxybutyric formed in diabetes though combined with fixed base to the extent of 100 per cent in the plasma with consequent reduction in the alkali reserve are excreted free in considerable quantities (acetoacetic 5 to 11 per cent, β -hydroxybutyric 20 to 55 per cent). Any acid excreted in the free state obviously represents a clear saving of the body's alkali. Palmer and Van Slyke state that the measurement of the increase in the excretion of total organic acids in diabetes is a reliable approximate guide to the quantity of acetone bodies (acetoacetic and β -hydroxybutyric acids) produced. The

¹² Hendrix and Sanders have shown that not only is base from the alkaline phosphate saved to the body, but that base from injected salts bound to acids as strong as hippuric is retained. The retention, it is believed, is effected not by the excretion to any extent of free hippuric acid, but by the substitution in the kidney of fixed base by ammonia as well as by the conversion of the di-basic phosphate to the mono-basic form. Such conversion is represented by the following reactions—

The base of salts of stronger acids such as sulphuric is not retained.

total quantity of organic acid (bound and free) excreted daily by a healthy man is between 240 and 600 cc. of N/10 organic acid (average of 6.0 cc. per kg. of body weight).

The third method by which fixed base is saved by the kidney is in the manufacture of ammonia (p. 391) for the neutralization of acids. The kidney separates certain acid radicals from the fixed bases with which they were combined in the plasma, joins them to ammonia, and excretes them as ammonium salts. In order therefore to arrive at a true estimate of acid excretion and the base saved to the body, the quantity of the ammonia excreted should be added to that of the titratable acid (titration to 7.4). The acid + ammonia value represents what may be termed the *base economy* exercised by the kidney. In health the daily excretion of ammonia amounts to from 300 to 500 cc. of N/10 ammonia. In severe diabetes it may be ten times this value. The hydrogen ion concentration, titratable acidity and ammonia of the urine usually vary together and in the same direction, though there is no exact proportional relationship. All three are determined by the relative concentrations of basic and acid radicals in the plasma. The value of the acid + ammonia excretion may therefore be employed as an approximate index of the lowering of the alkali reserve in such conditions as diabetes. The *ratio* of ammonia excretion to titratable acid in health

is usually 1 or over $\left(\frac{\text{NH}_3}{\text{titratable acid}} = 1 \text{ to } 2.5 \right)$.

In moderate degrees of kidney disease in which the urea concentrating function is impaired the ratio is low (0.1 to 0.7) owing to the fact that the power of the kidney to form ammonia is depressed while the excretion of acid is little altered. When however the renal insufficiency becomes extreme, the ratio may be higher than the impairment of renal function would lead one to expect. The rise in the ratio is due, not to an increase in the output of ammonia, but to a reduction in the excretion of acid. In the nephrotic type of nephritis in which there is no impairment of urea excretion the production of ammonia is not interfered with and the ratio is normal.

Fixed base enters the urine other than in combination with phosphoric acid. Sulphuric and hydrochloric acids formed during protein catabolism differ from phosphoric acid in that they are not excreted in the free state except in infinitesimal amounts but carry with them their full base equivalent, appearing in the urine as the neutral salts of either fixed base (NaCl , Na_2SO_4) or of ammonia (NH_4Cl , $(\text{NH}_4)_2\text{SO}_4$).

The *free carbonic acid* in the urine is small in amount (4.2 vols. per cent Gamble) and remains practically stationary at that of the plasma of the renal blood, passing into the urine by simple diffusion. It does not vary in amount with changes in urinary pH. The bicarbonate content of the urine, on the contrary, varies directly with the pH; in alkaline urines its quantity is large (up to 8 grams per liter), whereas in highly acid urines its quantity is negligible (0.02 gram per liter). When, therefore, the alkali reserve of the blood is normal or low, the urine is acid and practically no base is lost as bicarbonate. When, on the other hand, the bicarbonate of the plasma is above normal the urine is alkaline and large quantities of base pass into the urine as bicarbonate. Since the free carbonic acid remains unchanged at varying urinary pHs while

the bicarbonate content varies, the ratio $\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3}$ in

the urine varies with changes in pH.¹³ The ratio in urine on the acid side is from $\frac{1}{3}$ to $\frac{1}{4}$, whereas in neutral or alkaline urines it is from $\frac{1}{7}$ to $\frac{1}{100}$. The small quantities of free carbonic acid and bicarbonate present in acid urines render these "buffers" of negligible importance in determining the urinary pH as compared with the alkaline and acid phosphates. In alkaline urine the reverse is true, the carbonic acid—bicarbonate ratio being of primary importance.

The influence of starvation, diet, and of acid and alkali ingestion, upon urinary acid

Starvation increases the titratable acidity and ammonia, and lowers the pH of the urine. After exhaustion of the glycogen stores increased protein breakdown occurs with the production of phosphoric and sulphuric acids. As a result of the incomplete combustion of fat acetoacetic and β -hydroxybutyric acids are formed and excreted.

Diet. Cereals, meat and fish increase the titratable acid and ammonia of the urine and lower the pH. Most fruits (apples, pears, peaches, lemons, oranges, grapes, figs and raisins) contain the salts of organic acids; the acid radical undergoes oxidation in the body, the alkali being liberated. These fruits therefore tend to raise the alkali reserve of the plasma and to reduce the acidity of the urine. Plums, prunes and cranberries, on the contrary, increase urinary acidity since they contain benzoic and quinic acids which are converted to hippuric acid in the kidney. The herbivora normally pass alkaline urine, though if starved and so forced to use their body protein or if fed upon flesh, the urine becomes acid. The pH of the urine of men upon a purely vegetarian diet is from 5.30 to 7.48 with a mean of 6.64 instead of the usual mean of 6.0.

¹³ Since the H ion concentration of a solution containing H_2CO_3 and NaHCO_3 is a function of the ratio of the concentrations of these substances, if H_2CO_3 concentration remains stationary, variations in the concentrations of the other two must be inversely related.

Ingestion of acid and alkaline chemical substances. When acids such as sulphuric or hydrochloric, or acidifying salts (CaCl_2 , NH_4Cl , $(\text{NH}_4)_2\text{SO}_4$) are taken by mouth in large amounts, a reduction in the alkali reserve of the plasma, an increase in the total excretion of phosphate, chiefly of the mono-basic salt, a rise in the titratable acidity and a fall in pH of the urine result. The urinary ammonia increases. The following reaction results from the absorption of hydrochloric acid.

A proportion of the Cl^- radical is excreted in the urine as NaCl and so entails an equivalent loss of fixed base. Some excretion of acid over basic substances is effected by the excretion of a greater proportion of the mono-basic phosphate. This factor, however, is limited since at the usual reaction of the urine 90 per cent of the dibasic phosphate has already been converted to the mono-basic form. Also, the body's available stores of phosphate after a time become exhausted; the excretion of acid by this means must then come to an end. It has been pointed out that normally a most important factor in the elimination of acid radicals and the conservation of fixed base is the production of ammonia by the kidney; after the ingestion of HCl a part of the Cl^- is excreted as the ammonium salt.

Similar changes to those just described follow the ingestion of CaCl_2 or of NH_4Cl in large doses. In the case of calcium chloride ingestion Cl^- displaces HCO_3^- from the bicarbonate of the body fluids according to the following equation.

The NaCl and CaCO_3 are excreted. There is thus a net loss of base from the body; a severe acidosis results. The calcium is excreted mainly in the feces, though it is possible that a proportion is also deposited in the bones, since calcium in the form of the chloride when fed to dogs cannot all be recovered from the excreta. As in the case of HCl ingestion, Cl^- is also excreted in the urine combined with ammonia.

The acidifying effect of NH_4Cl is probably due to the conversion of NH_4 to urea, the Cl^- radical being freed. When 20 grams or so of NH_4Cl are administered the urinary excretion of urea and of sodium chloride rises abruptly. The reaction is shown as follows:

The HCl then reacts with bicarbonate of the plasma with the production of sodium chloride and carbonic acid. The passage of the large quantities of base into the urine when calcium chloride or ammonium chloride are administered requires the excretion of large quantities of water. These two salts therefore act as powerful diuretics and agents for the removal of edema fluid. When large quantities of acid-sodium phosphate are ingested, though there is a great increase in the titratable acidity of the urine, no change in ammonia excretion

occurs. Since this salt can be excreted as such there is no call apparently for the production of ammonia for the conservation of base such as occurs after the ingestion of hydrochloric and other acids.

The effects of the *administration of alkalis* are, as might be expected, the reverse of those following the ingestion of acid substances. Large doses of bicarbonate augment the alkali reserve, reduce the excretion of total phosphates, and increase the proportion of those in the di-basic form. The excretion of the titratable acid plus ammonia falls while the bicarbonate content and pH of the urine rise. Though large doses (45 grams daily) of bicarbonate are required to render the urine alkaline and keep it so, a wave of urinary alkalinity will result from the administration of much smaller doses. Palmer and Henderson make use of this fact in their *bicarbonate tolerance test* for reduction in alkali reserve. Four grams of sodium bicarbonate when administered to a normal person cause a perceptible rise in urinary pH, whereas larger doses are required to produce a similar effect in one with a lowered alkaline reserve. A similar clinical test has been devised by Sellards. These tests are of value in some conditions, but in nephritis the power of the kidney to excrete bicarbonate may be impaired, under which circumstances the test would indicate a lower alkaline reserve than actually existed. In diabetes also the test may indicate acidosis in its absence. For these reasons more reliance may be placed upon the test when it is negative (i.e., when it indicates a normal alkaline reserve) than when it is positive. Salts of organic acids—acetates, citrates, lactates—are also alkalinizing in their action; the organic acid radical is oxidized, the base joining with H_2CO_3 to form bicarbonate.

The "alkaline tide" of the urine

Leathes found that the urine passed a short time after rising in the morning was less acid than that formed during sleep. This change in urinary reaction is spoken of as the *morning alkaline tide*. (The urine does not necessarily become alkaline but may only become less acid—an elevation in pH or decreased titratable acidity.) The greater acidity of the night urine over the urine of the early waking hours was ascribed by Leathes to depression of the respiratory center during sleep and the retention of carbon dioxide. The increased pulmonary ventilation which occurred after rising supposedly removed carbon dioxide, the effect upon the acid base balance being reflected in the reduced acid excretion by the kidney.¹⁴

¹⁴ Brunton points out that the acid output per minute, that is, the titratable acidity value multiplied by the urine volume (cubic centimeter) per minute is a more reliable index of acid excretion than simply the titratable acidity per unit volume of urine. The latter may be reduced as a result of diuresis without the actual quantity of acid secreted in a given time being altered.

Leathes found that samples of alveolar air taken immediately upon awakening had a higher percentage of carbon dioxide (6.8 per cent) than those taken an hour or so after rising (CO_2 , 5.7 per cent.) It has been shown by Hubbard, however, that merely awakening causes a rise in urinary pH which may be actually higher than after getting out of bed. Now, it is well known that a change in the reaction of the urine towards alkalinity may be demonstrated by voluntary forced breathing. (If the forced breathing is continued for some time the urine may become alkaline to litmus, the bicarbonate content is increased, the acid + ammonia is reduced and acetone bodies may appear.) Nevertheless, since the morning alkaline tide is more pronounced immediately after waking than later when the exercise of dressing, etc., should increase the pulmonary ventilation, the mechanism underlying the fall in urine acidity is not so simply explained. It is associated in some unexplained way with respiratory changes incident to the return of consciousness.

An alkaline tide also occurs within an hour after a meal—*postprandial alkaline tide*. The titratable acidity and ammonia excretion are reduced and the urinary pH rises.

A rise in the CO_2 tension of the alveolar air was first shown by Higgins to occur almost immediately after taking food. Dodds found the rise to amount to from 2 to 6 mm. Hg, and Van Slyke, Stillman and Cullen observed a corresponding rise in the plasma bicarbonate. These changes—reduced excretion of acid by the kidney and retention of carbon dioxide—have been generally attributed to compensatory adjustments in the acid base balance resulting from the loss of hydrochloric acid in the gastric juice. Dodds also reported a fall in alveolar CO_2 tension in from one to two hours after a meal, which was put down to the secretion of alkali in the pancreatic juice. The view that gastric secretion is the cause of the alkaline tide of the urine was supported apparently by the fact that it was most pronounced after the ingestion of meat—a powerful gastric stimulant—whereas it was much less likely to appear after a meal of carbohydrate or fat. Nevertheless, there are many difficulties in the way of accepting this view. A well-marked alkaline tide following meals has been observed in subjects of achlorhydria. Brunton and Wilson, on the other hand, have produced good gastric secretion in subjects by means of a meal of Bovril without any decrease in the total excretion of acid by the kidney. Brunton and Israels also report that a rise in

alveolar CO_2 tension or an increase in the quantity of CO_2 expired per minute does not, as a rule, occur when a profuse secretion of gastric juice is induced by the injection of histamine. A fall in CO_2 tension after a meal coincident with the calculated time of pancreatic secretion was not observed. Such observations strongly oppose the idea that the rise in alveolar CO_2 tension following meals is a consequence of gastric secretion. It is more likely connected in some way with the drowsiness and the reduction in pulmonary ventilation which occurs at this time. Main attributes it to the removal of the stimulating effect of the hunger contractions on the respiratory center. It is also improbable, on theoretical grounds, that the loss of HCl is a factor, since pancreatic secretion follows so closely upon gastric secretion that one effect would be expected to balance the other. These remarks also apply to the postprandial alkaline tide of the urine. Possible additional factors in the production of the latter are excess of basic over acid radicals absorbed from the food itself or the sparing effect of the meal upon protein catabolism. In some instances the decreased urinary acidity is simply due to diuresis, the acid content per unit volume of urine being reduced without any change occurring in the total acid excretion.

THE VOLUME OF THE URINE

The quantity of urine excreted in 24 hours by a healthy adult under ordinary circumstances is between 1000 and 1800 cc. The normal kidney may, depending upon the requirements at the time, eliminate per hour as little as 25 cc. of fluid or as much as 1200 cc. Usually from 40 to 60 per cent of the total fluid intake of the 24 hours is excreted by the kidneys, but the quantity of urine formed must necessarily vary inversely with the quantity of fluid eliminated by other channels,—lungs, skin and bowels. Diet, the quantity of fluid drunk, environmental temperature and humidity, posture, exercise, mental excitement, weight, age and sex, are among some of the physiological factors which influence the urine volume. The output is greater upon a high than upon a low protein diet, the end products of protein metabolism exerting a diuretic effect. High temperature, especially if accompanied by visible sweating, reduces the urine volume. Muscular exercise has a similar effect. The volume is greater in the recumbent than in the erect posture (p. 382). Young children excrete for their weight from 3 to 4 times more urine than adults. The

urine volume is reduced below the normal in cardiac failure, in fevers, in acute nephritis and in the later stages of chronic nephritis. The volume is markedly increased in diabetes insipidus (p. 739) and in diabetes mellitus. (For the action of diuretics, see page 389.)

The urine of the day (8.30 a.m. to 8.30 p.m.) is normally from 2 to 4 times greater in amount than that secreted during the night (8.30 p.m. to 8.30 a.m.). This ratio holds even though the quantity of fluid drunk during both periods is the same. In normal night workers the ratio is reversed. An increase in the night urine of a day worker to an amount approaching that of the day period should suggest renal insufficiency (*nycturia* or *nocturia*).¹⁵ In many cases of renal disease the night urine exceeds the day urine in volume. The terms *polyuria* and *oliguria* are applied respectively to the excretion of supernormal and subnormal quantities of urine. Total cessation (suppression) of urinary excretion is termed *anuria*.

The influence of the pituitary upon the urine volume is dealt with in Chapter LXL (See also p. 390 and p. 397.)

SPECIFIC GRAVITY OF THE URINE

The specific gravity of the urine under the ordinary conditions of health varies between 1.015 and 1.025 and inversely with the urine volume. A urine of large volume usually has a lower percentage of total solids and consequently a lower specific gravity than one of small volume. Upon a very high fluid intake a urine with a specific gravity of 1.001 may be passed. The urine excreted upon a low fluid intake, or when much fluid is lost through other channels, skin and bowels, may have a specific gravity as high as 1.030. In pathological conditions this relationship between specific gravity and volume does not necessarily hold, for large quantities of urine with a very high specific gravity (1.040 or more) are eliminated in diabetes mellitus, whereas in chronic nephritis a urine of small volume and of low specific gravity (1.010) may be excreted. Though the fluid intake be rigidly restricted a kidney whose function is seriously impaired may be unable to concentrate the urine sufficiently to raise the specific gravity above 1.010 or so. Furthermore, when the fluid intake is high the production of urine of very low specific gravity (1.008 or lower), a feat readily accomplished by the normal kid-

ney, is beyond the powers of a seriously diseased kidney. Variability of function according to the needs of the moment is one of the most pronounced characteristics of the normal kidney. The diseased kidney on the contrary is unable to vary the specific gravity of the urine over a wide range; its ability to alter the volume of the urine is also very greatly impaired. The specific gravity of the urine in health is directly proportional to the concentration of its dissolved solids (chiefly chlorides and urea).

A rough method of determining the total urinary solids is to multiply the last two figures of the specific gravity by 2.66 (Long's coefficient). This gives the quantity of total solids in grams per liter. This method is not reliable for some pathological urines, since different substances vary in the extent to which they contribute to the specific gravity of a solution; it is clear that should the urine contain abnormal constituents (albumin, sugar) or should the proportions of its normal constituents be altered greatly, the relationship between total solids and specific gravity just expressed will not hold. Less than 1.5 grams of NaCl, for instance, will produce as great a rise in specific gravity of the urine as nearly 4 grams of albumin. The latter unless present in relatively large quantities will therefore have little effect upon the urinary specific gravity. The following table (after Albarran) gives the amounts of several substances which are required to be added to a liter of urine in order to raise its specific gravity 0.001:

	grams
Urea.....	3.6
Glucose.....	2.7
Acid sodium phosphate.....	3.8
Sodium chloride.....	1.47
Albumin.....	3.9

COMPOSITION OF THE URINE

In the following table are given figures for the average amounts of inorganic and organic solids in 1000 cc. of urine of a healthy adult on an ordinary mixed diet. The total solids amount to from 40 to 50 grams per liter, the urea constituting about one-half of this.

I. Inorganic constituents

	Volume 1000 cc. grams
(a) Chloride expressed as NaCl.....	9.0
(b) Phosphorus expressed as P ₂ O ₅	2.0
(c) Total sulphur expressed as SO ₃	1.5
(d) Sodium expressed as Na ₂ O.....	4.0
(e) Potassium expressed as K ₂ O.....	2.0
(f) Calcium expressed as CaO.....	0.2
(g) Magnesium expressed as MgO.....	0.2
(h) Iron.....	0.003

¹⁵ An increase in the volume of night urine above 500 cc. and with a specific gravity less than 1.018 is usually defined as *nycturia*.

II. Organic constituents

ZNOUS.

..... 25.0 grams containing, approximately, 10.0 gram nitrogen

nia..... 0.6 gram containing, approximately, 0.4 gram nitrogen

cid..... 0.6 gram containing, approximately, 0.2 gram nitrogen

nine..... 1.5 grams containing, approximately, 0.5 gram nitrogen

etermined

ogen¹⁸..... 0.6 gram

total..... 11.7 grams nitrogen

ea, ammonia, and the inorganic and sulphates (pp. 509 and 551) vary with content of the diet whereas the cre- and neutral sulphur, particularly the e little affected by the level of the pro- e (see also table 48, p. 550).

ORGANIC SUBSTANCES PRESENT IN SMALL QUANTITIES OR MERELY IN TRACES:

ments, e.g., urochrome and urobilin, (traces of the latter only).

gar, minute amounts (2 to 3 mg. per cent) of fermentable sugar are found in the urine in 50 per cent of normal persons after the noon meal (Harding and associates).

etty acids; aceto-acetic and β -hydroxybutyric acids.

arbonates, bicarbonates and free carbonic acid.

acin and mucin-like substances.

astase.

rus is found in the urine largely combined with sodium as the *mono-sodium* and *di-phosphates* NaH_2PO_4 and Na_2HPO_4 , and to a lesser extent with potassium to form the *potassium salts* of this mineral. About three-fourths of the total urinary phosphorus exists in these forms. A small quantity is possibly present as $\text{NH}_4\text{H}_2\text{PO}_4$. The remaining quarter of the total phosphate is present as salts of the *alkaline earths*, calcium and magnesium, as $\text{Ca}(\text{H}_2\text{PO}_4)_2$ and $\text{Mg}(\text{H}_2\text{PO}_4)_2$. These earthy phosphates are insoluble in alkaline urine and are precipitated (phosphate deposit) when, as a result of bacterial action the urea of urine which has stood for some time after voiding becomes decomposed with the formation of ammonia. Infection of the genito-urinary tract may for the same reason produce an alkaline urine which is clouded when voided by precipitated phosphates. In perfectly healthy persons urine which, as a result of a diet rich in alkaline carbonates, is alkaline in reaction may be cloudy when passed owing to the production of the insoluble phosphates of calcium and magnesium $\text{Ca}_3(\text{PO}_4)_2$ and $\text{Mg}_3(\text{PO}_4)_2$. The condition is called *struvite*.

posit) when, as a result of bacterial action the urea of urine which has stood for some time after voiding becomes decomposed with the formation of ammonia. Infection of the genito-urinary tract may for the same reason produce an alkaline urine which is clouded when voided by precipitated phosphates. In perfectly healthy persons urine which, as a result of a diet rich in alkaline carbonates, is alkaline in reaction may be cloudy when passed owing to the production of the insoluble phosphates of calcium and magnesium $\text{Ca}_3(\text{PO}_4)_2$ and $\text{Mg}_3(\text{PO}_4)_2$. The condition is

FIG. 178. Heart-lung-kidney preparation. The continuous line represents the rate of urine flow in cubic centimeters per fifteen minutes, the broken line the chloride concentration in the urine. The polyuria and fall in chloride concentration of the urine characteristic of the preparation are clearly shown. At G the head of another dog was included in the perfusion circuit, so that the blood passed through the pituitary as well as through the heart and kidney. A pronounced fall in urine volume and a rise in chloride concentration then occurred. Removal of the head (at H) was followed by a return of the polyuria and a fall in chloride concentration. (After Verney.)

called *phosphaturia* and is quite physiological. The relative proportions of the mono-basic and di-basic phosphates determine the hydrogen ion concentration of normal urine (p. 391). The urinary excretion of inorganic phosphorus is determined by the level of the plasma inorganic phosphorus.

The total phosphate content of the urine is increased under several conditions,—lowered alkali reserve, starvation, high protein diet, severe muscular exercise, in gout and following the administration of large doses of parathyroid extract. It is increased by such diuretics as sodium nitrate and sulphate, and by calcium and ammonium chlorides, but not by water diuresis.

The urinary P is low in the morning but rises in the later hours of the day, reaching a maximum in the night urine. Though the great part of the urinary P is derived from the inorganic P of the plasma, a small part (6 per cent) is organic (glycerophosphates, hexose-phosphates, nucleotides). The kidney is rich in *phosphatase* (p. 716) yet it does not seem that any considerable part of the inorganic P of the urine results from the action of this enzyme upon organic phosphorus compounds of the plasma. The urinary P is *reduced* in pregnancy; when the alkaline reserve is high, in renal insufficiency, tetany and in certain bone diseases. Insulin causes a marked fall in the urinary P for the first six hours following the injection, and a rise for the next six hours. The work of Brull and Eichholtz suggests that the pituitary or hypothalamic region of the brain is concerned in the excretion of inorganic P by the kidney. This was suppressed by removal of the gland or by injury to the tuber cinereum, yet no corresponding change in the level of plasma P (organic or inorganic) occurred¹⁷.

The *chloride* of the urine (chiefly in the form of NaCl) is derived almost solely from the chlorides of the food. The concentration of chlorides in normal urine varies from 0.5 to 2.0 grams (as NaCl) per 100 cc. as compared with about 0.6 per cent in the plasma. Chloride is a high threshold substance and in prolonged starvation or upon a salt-free diet, though the urine may be practically chloride-free, the chloride of the blood remains at or but slightly below the normal level. When chloride is lost through vomiting, the urinary chloride is reduced: the Cl lost in the vomitus being derived from the blood NaCl, results in an excess of base (Na) being left in the plasma; this combines with H_2CO_3 to increase the bicarbonate reserve. In pneumonia, cardiac failure or renal disease with edema, intestinal obstruction, severe diarrhea, and many acute febrile conditions the urinary chlorides are markedly reduced. In lobar pneumonia after the injection of large quantities of sodium chloride only small quantities appear in the urine; the injected salt is retained until after the crisis.

The experiments of Verney and Starling indicate that the posterior lobe of the pituitary gland

exerts a specific effect upon the urinary excretion of chloride by the kidney. These observers found that a kidney, perfused by means of a heart-lung preparation (heart-lung-kidney preparation) excreted large quantities of urine with a very high chloride concentration. The addition of pituitrin to the blood circulating through the organ increased the urine volume; the percentage of chloride in the urine and the total quantity excreted increased. Verney also studied this question upon a heart-lung-kidney preparation in which the blood could be switched at will through the legs or through the head of another animal. In the former instance, the urinary secretion was profuse and of low chloride concentration. When the blood was passed through the head the secretion of water was reduced and the percentage of chloride, and in some instances its absolute amount, rose (fig. 178). Something had evidently been added to the blood during its passage through the head which brought about this effect. If the pituitary had been removed previously the incision of the head and neck in the circulation was without influence upon the chloride excretion (see also Diabetes Insipidus, pp. 731 and 739).

The maximal concentrating power of the kidney for chloride is 0.333 molar. Pituitrin is not capable of raising the chloride concentrating power of the normal kidney above this maximum value.

Sulphur occurs in the urine in three forms: (a) *inorganic sulphates*, (b) *etheral sulphates*, and (c) *neutral sulphur* (see p. 585).

Urochrome (Thudichum) is the normal urinary pigment. Its chemical constitution and the nature of its precursor are unknown. Its output was found by Drabkin to be remarkably constant from day to day under the ordinary conditions of health. The output is independent of diet but bears a relation to the level of the basal metabolism. It is therefore endogenous. In fevers, hyperthyroidism, and as a result of elevating the metabolic rate by the administration of thyroxine or adrenaline its output is increased. The output of urochrome is also increased by tissue breakdown, by starvation or by the administration of acids. Thyroid extirpation reduces its elimination below the normal level in animals, and to the normal level in subjects with exophthalmic goiter.

¹⁷ Except in the alkalosis and hyperphosphatemia of pyloric stenosis when the urinary P is increased.

CHAPTER XXXVII

THE PATHOLOGICAL PHYSIOLOGY OF KIDNEY DISEASE MICTURITION

Classification of kidney diseases

A logical classification of kidney disease would be based upon the nature (inflammatory or degenerative) and the site (glomeruli, tubules or both) of the renal injury, and which would make a correlation to be established, through knowledge of renal physiology, between such injury and the signs and symptoms of the disease. An ideal is impossible of attainment, for though a certain part of the renal structure at one time bears the brunt of the disease, there is a tendency for other parts of the kidney to become secondarily involved, if not in anatomical changes, at least in function. For this reason, as well as from the fact that extrarenal factors (cardio-vascular) may become disturbed to such an extent as to affect renal function, the signs and symptoms of chronic kidney disease are extraordinarily variable; mixed forms of nephritis rather than pure types are common. Nevertheless, a classification based upon the nature of the primary pathological process (inflammatory, degenerative, arteriosclerotic) and the type of renal structure primarily affected will be given. Where possible an attempt will be made to explain signs and symptoms by the application of physiological principles. There are three main types of renal disease:

Glomerulo-nephritis is essentially inflammatory in nature, and the glomeruli are primarily affected.

The *nephroses* are the result of a degenerative process involving the tubules.

Arteriosclerotic kidney disease. The large and small renal vessels are the seat of sclerosis.

GLOMERULO-NEPHRITIS

Glomerulo-nephritis is seen in an acute and a chronic form.¹ Though the chronic type is usually thought to be nearly always initiated by the acute disease, the latter may have been so mild as to have escaped notice. So, chronic glomerulo-nephritis often appears to have arisen *de novo*. The acute disease, and so the chronic form into which it merges, is thought to be usually due to a subacute form—a transition stage between the acute and chronic forms—is recognized.

to the toxin of some streptococcal or pneumococcal infection, e.g., sore throat, scarlet fever, influenza, etc.

ACUTE GLOMERULO-NEPHRITIS

In the acute disease the glomeruli show inflammatory changes which vary in intensity in different cases. When the disease is severe, the following histological picture is seen. Great numbers of the glomerular capillaries are dilated and filled with a coagulated exudate containing a few leucocytes but almost free from red cells. These capillary plugs completely obstruct the flow of blood through a large proportion of the glomeruli. The endothelial cells of the capillaries according to most pathologists show active proliferation, producing masses which project into the vascular lumina. The entire tuft is swollen and may almost fill Bowman's capsule. There is often an exudation of leucocytes into the interstitial tissue around the glomeruli. Bowman's capsule and the tubules contain masses of exudate and red cells, but the tubular epithelium itself, shows little abnormality as a rule, beyond some slight cloudy swelling or fatty change.

Such a severe reaction must of course if wide spread cause a high degree of renal insufficiency. The following are among the chief features of the disease: retention in the blood of non-protein nitrogenous products (p. 402); edema; hypertension (p. 128) with perhaps cardiac dilatation; acidosis; anemia; hematuria; albuminuria and casts (hyaline, blood, granular and epithelial), and the passage of a small quantity of urine with a high specific gravity. The majority of cases are much milder than this but all degrees of severity are encountered. Uremia occasionally terminates acute nephritis. In most instances however, recovery occurs, or the disease progresses to the sub-acute or chronic form. Neither the intensity of the acute attack nor the degree of nitrogen retention offers a reliable guide to prognosis.

CHRONIC GLOMERULO-NEPHRITIS

The histopathology varies according to the stage of the disease, but in general the picture is one of a healing or a healed inflammatory lesion of the glomeruli. Many of the latter show occlusion and hyaline degeneration of some or of all their

capillary loops; others are replaced by fibrous tissue, and yet others may show compensatory hypertrophy. Proliferation of the cells of Bowman's capsule is often a prominent feature. Sooner or later the tubules are the seat of hyaline or fatty changes; their epithelium becomes flattened and their lumina dilated. Some tubules may show attempts at regeneration, masses of newly formed epithelial cells appearing here and there. Glomerular regeneration is never seen. Sclerosis of arterioles and hypertrophy of their muscular coats are found in the later stages and are probably the result of the sustained hypertension which is such a common feature of the disease. Some vessels may show obliteration of their lumina as a result of active proliferation of their lining cells (endarteritis obliterans). In the following table is given a summary of the characteristic clinical features of chronic glomerulo-nephritis. Compare with table on page 401.

(a) *Albuminuria*, usually not excessive (from 2 to 10 grams per day). Albumin-globulin ratio between 3 and 10 (p. 405). Epithelial, blood, hyaline and granular casts

(b) *Renal insufficiency* (see p. 402); reduced ammonia production and consequent fall in the ammonia-acid ratio; *acidosis*

(c) *Edema* is often absent; when present it is not so prominent a feature as in nephrosis. Reduction of plasma protein and chloride retention are also less pronounced than in nephrosis.

(d) *Hypertension, cardiac hypertrophy and retinal changes* (see p. 128).

(e) Large urine volume (*polyuria*) in earlier stages, *nycturia*; reduced volume (*oliguria*) in later stages; urine of low specific gravity, tending to become fixed around that of deproteinized plasma (1.009 to 1.011). There may be *glycosuria*.

(f) *Anemia*.

(g) *Uremia* usual cause of death.

Kidney disease showing the foregoing features is sometimes spoken of as the *azotemic type*, after the clinical classification introduced by continental authorities.

Though the disease under discussion is primarily a glomerulitis, it will be recalled that the blood supply of the tubules is dependent almost solely upon the glomerular capillaries. At first only a proportion of the capillary loops in a given tuft may be involved in the inflammatory process. The total available filtering surface will be reduced thereby, but the tubules may still be adequately supplied with blood through pervious capillaries. Later, when the glomerular flow becomes greatly

curtailed, the tubules of that nephron undergo degeneration and atrophy. This is the reason, no doubt, that the concentrating function of the kidney (re-absorption of water) becomes impaired in glomerulo-nephritis. The reduced ammonia production, as well as the glycosuria and the fall in the serum calcium which sometimes occur in the disease can also be attributed to tubular involvement; the excretion of sugar and of calcium shows a striking increase (reduced re-absorption) when the tubules are poisoned by uranium in experimental animals.

In some instances, chronic glomerulo-nephritis during its earlier stages shows signs and symptoms almost identical with those of chronic lipoid nephrosis (p. 401), nitrogen retention, hypertension, etc., not appearing until later in the course of the disease. It is then referred to as the *nephrotic type of glomerulo-nephritis*. Edema is a prominent feature. In such cases, apparently, the action of the toxin at first has been upon the tubules which undergo degenerative changes, the effect upon the glomeruli at this time being relatively mild.

NEPHROSIS

(Synonyms: *tubular nephritis, degenerative Bright's disease, parenchymatous nephritis*)

This term embraces those several diseases of the kidney, acute, subacute or chronic, mild or severe, in which the predominant lesion is a *degenerative* one, implicating the *tubular epithelium*. Whereas the toxin of scarlet fever, for instance, acts primarily as a glomerular poison, several other toxic substances act chiefly in causing nephrosis. In many fevers albuminous degeneration (cloudy swelling) of the tubular epithelium occurs, and albumin appears in the urine but disappears after the fever has subsided. This is referred to as *febrile nephrosis*. Degenerative changes (albuminous, fatty) of varying degrees of intensity occur in *diabetes, malaria, pernicious anemia, pregnancy, obstructive jaundice, intestinal obstruction*, etc. *Chemical poisons*, e.g., salts of mercury, chromium, bismuth, uranium, lead and arsenic, methyl alcohol, carbolic acid, etc., may produce mild or severe degenerative changes in the tubules. *Amyloid nephrosis*; in pulmonary tuberculosis chronic pyogenic infections (e.g., osteomyelitis) the tubules show amyloid degeneration and atrophy. Many of the glomerular tufts may also be obliterated by amyloid deposits. The renal arterioles may show similar changes. Not only

lyloid nephrosis, but in some of the other more severe forms, e.g., those due to chemical poisons, the glomeruli may be involved in the degenerative changes, though usually to a much less degree than the tubules.

The clinical manifestations of the different types of nephrosis vary widely. Many are of mild degree and of a temporary nature; a small amount of albumin and a few casts are present in the urine and renal insufficiency is absent. The more severe and chronic forms are as a class characterized by *edema, a high degree of albuminuria, reduction of plasma protein (mainly of the albumin fraction) lipemia and hypercholesterolemia and the absence of hypertension and renal changes*. Except in very severe acute types, such as those caused by chemical poisons in which necrosis of the tubular epithelium may occur accompanied by anuria, renal insufficiency is absent or of moderate degree.

LIPOID NEPHROSIS

(Synonym: *genuine or pure nephrosis*)

This is an exceedingly rare disease, and did it not possess certain features of great clinical and physiological interest its description in a book of this nature would scarcely be justified. The cause of this condition is obscure, though in a certain proportion of cases syphilis appears to predispose to it. The histopathology is one of a pure degenerative disease of the tubular epithelium. The glomeruli are usually normal in appearance, as are also the arterioles and larger vessels. The degenerative change consists of the deposition of anisotropic lipoid material (cholesterol esters) in the tubular cells and interstitial tissue. Cloudy swelling, necrosis or calcification of the epithelium are less characteristic changes. The clinical features are chiefly those given above as characteristic of the chronic nephroses.

- 1) *Edema*, frequently massive with *ascites*, protein content of edema fluid low (0.1 per cent). Low plasma albumin (less than 2.5 per cent) and total protein (less than 5 per cent).
- 2) *Albuminuria*, often excessive (5 to 20 grams or more daily); albumin-globulin ratio in urine high (1 to 20) and low in plasma (see p. 406).
- 3) *Urine* of small volume, of normal or high specific gravity and low in chlorides when edema is present. During recession of the edema the urine volume increases, the specific gravity falls and the chloride excretion rises. Hematuria is absent.
- 4) Absence of hypertension, cardiac hypertrophy and retinal changes.
- 5) *Lipemia* and *hypercholesterolemia* (up to 1000 mg. or more per 100 cc.); lipoid droplets in the urine.

(6) *Low metabolic rate*.

(7) *Absence of renal insufficiency*; uremia does not occur; death usually results from some intercurrent infection, especially peritonitis (pneumococcal).

The cause of the disease is unknown. Two views are held: (a) that it is primarily a degenerative disease of the renal tubules resulting from an unknown toxin; (b) that it is a general metabolic disease of which renal manifestations are merely a part. Epstein believes that the protein in the urine differs from the normal plasma protein, being excreted as any "foreign" protein would be. Several observers have reported differences between the serum proteins of nephrotic patients and those of normal persons. The albumin fraction of the serum in nephrosis was found by Tuchman and Sobotka to contain more tyrosine than normal and the globulin less; and Alving and Mirsky obtained from nephrotic serum an albumin fraction with a cystine content below that in normal serum albumin. The albumin of the protein excreted in the urine was found to contain more cystine than did the corresponding serum protein, but less than that present in normal serum albumin. Bourdillon found from osmotic pressure determinations that the serum proteins of patients with nephrosis had molecular weights from 50 to 100 per cent greater than the normal, whereas, the urinary proteins were lighter than those of normal serum. The molecular weights as determined will of course be average values and Bourdillon offers the explanation that the molecules are of variable sizes, some much larger and others smaller than those of normal serum proteins, and that the glomerular membrane is permeable to the latter but not to the former.

ARTERIOSCLEROTIC KIDNEY DISEASE

(Synonym: *nephrosclerosis*)

This occurs in three forms. (1) In elderly persons the *larger renal arteries*—arcuate, interlobular or interlobar—are chiefly involved in sclerotic changes as part of a general systemic arteriosclerosis. As a result of closure of some of these branches the blood supply may be shut off from relatively large renal areas (infarction). The nephrons within these areas atrophy and the reserve of the kidney becomes reduced. This is a picture of the *senile kidney*. The changes as a rule give rise to nothing more than a mild degree of renal insufficiency. The condition is of no great clinical or physiological interest.

(2) The *renal arterioles* become sclerosed (proliferation of their endothelial cells and a thickening of their muscular coats) as a sequel to *essential hypertension*.

The persistent high pressure is looked upon as the direct cause of the arteriolar changes. The closure of numbers of afferent vessels causes a wide-spread destruction of glomerular tufts which become hyalinized or replaced by fibrous tissue. Degenerative changes occur in the tubules and the interstitial tissue is increased. Renal insufficiency results. When renal symptoms supervene they resemble those of chronic glomerulo-nephritis, but tend to be overshadowed by the primary cardiovascular features. The following are the main differences between this type and glomerulo-nephritis.

(a) Renal insufficiency is not, as a rule, a prominent feature until congestive heart failure supervenes.

(b) Albuminuria slight, absent or intermittent.

(c) Edema a less pronounced feature and usually of cardiac origin.

(d) Greater degree of hypertension and cardiac hypertrophy.

(e) Death usually due to cardiac failure or cerebral hemorrhage.

(3) As a result of *malignant hypertension* (p. 136) the renal arteriolar disease is more intense. Endarteritis and necrosis of the afferent vessels (*malignant nephrosclerosis*) cause a more rapidly progressive destruction of the glomerular tufts. Renal insufficiency develops acutely.

THE PATHOLOGICAL PHYSIOLOGY OF SOME OF THE MAIN FEATURES OF RENAL DISEASE

I. RENAL INSUFFICIENCY

Renal insufficiency means a reduced capacity of the kidney to carry out its functions, namely;—

(a) *The excretion of non-protein nitrogenous substances*—urea, uric acid, creatinine, etc. The rate of excretion of urea is directly proportional to (i) its concentration in the blood when the urine volume is above a certain limit—*augmentation limit* (p. 404). Consequently, when the rate of excretion of urea tends to fall as a result of kidney damage, its concentration in the blood rises and the excretion becomes established at a higher level, (ii) the square root of the urine volume when this is below the augmentation limit, and (iii) the amount of active renal tissue when this is less than about 50 per cent of the normal.

(b) *The excretion of water*. Though there may be polyuria (p. 408) which might suggest that there is no incapacity of the kidney to eliminate water, it will be found that the inefficient kidney cannot respond promptly when an extra demand is made upon this function. Consequently, when a large quantity of water is drunk it is not excreted within the normal time. Furthermore, the specific gravity of the urine does not fall to the low level (1.001 to 1.003) of urine formed in health under the same circumstances, but remains around that of

deproteinized plasma (glomerular filtrate), namely, 1.009 to 1.010.

(c) *Concentrating power* (re-absorption of water) is impaired. The low threshold substances, such as urea, uric acid, etc., are in lower concentration in nephritic than in normal urine even when the concentrating power of the kidney is encouraged by reducing the fluid intake. If fluids are withheld for some time from a healthy person, he passes urine of a high specific gravity, 1.030 or over. The severely impaired kidney is unable to raise the specific gravity much, if at all, above that of protein-free plasma. Taking the two last mentioned functions, (b) and (c), together it may be said that as the renal injury progresses, the specific gravity of the urine after the ingestion of a quantity of water tends to be depressed less and less toward the normal figure of about 1.002; when fluid is withheld the specific gravity is raised with increasing difficulty toward the normal maximum of about 1.030. In other words, instead of showing the great swings in specific gravity of normal urine under varying conditions of fluid intake, nephritic urine tends to become fixed at a specific gravity around 1.010. *Hyposthenuria* is the term used to denote sub-normal concentrating power. *Isothenuria* is a term which means that the kidney cannot form urine with a higher or lower specific gravity than that of protein-free plasma.

When one speaks of renal insufficiency it is the impairment in the functions referred to in the foregoing paragraphs that is meant, since it is for the measurement of the degree of impairment of these functions that the most reliable methods have been devised. Yet, it should be remembered that renal disease does not single out any particular function for attack; when one is impaired others also suffer more or less. *Nitrogen excretion, water elimination, concentrating power, ammonia and hippuric acid production, and base conservation* (p. 392) are all interfered with more or less together. There is one apparent exception; the leakage into the urine of serum protein—proteinuria—which is an indication of some abnormality of the glomerular membrane, may be present in the absence of other signs of disturbed renal function (see *lipoid nephrosis* and *benign albuminuria*). Proteinuria, therefore, though a fault in renal function is not a criterion of renal insufficiency in the ordinarily accepted sense of this term.

Renal insufficiency may be *relative*, as when there is an accumulation of nitrogenous products in the blood, and water elimination is difficult

protein diet which will encourage the regeneration of plasma protein would appear, therefore, to be a rational procedure in the treatment of nephrotic edema. It also follows that it is undesirable to remove large quantities of edema, or ascitic fluid mechanically (paracentesis) for, though the protein content of the fluid is very low, the total amount lost to the body through such a procedure may be significant.

The question of water and salt retention

It was thought at one time that edema was due to the inability of the kidney to excrete water and salt. The blood volume was believed to increase as a result of the water retention. Increase in the blood water (hydremia) was also encouraged, apparently, by the retention of salt, since the accumulation of water would tend to restore the normal osmotic pressure of the body fluids. Recent work has shown that in lipoid nephrosis, in which edema is a prominent feature, the kidneys have no difficulty in excreting water or chloride, for though the urine is of small volume and low in chloride while the edema is forming, when this subsides after treatment, large quantities of water and salt are eliminated. Even in the nephrotic type of glomerulo-nephritis, though there is impaired water excretion, this is not the primary cause of the edema, and the ability of the kidney to excrete chloride is little if at all reduced; the sodium chloride of the blood may be normal or even below normal and sodium chloride injected intravenously actually disappears from the blood of the nephritic subject more quickly than from the blood of a normal person. On the other hand, when the excretion of water and salt is entirely prevented, as during suppression of urine, the blood chloride rises yet edema does not necessarily occur. Direct estimations indicate that the plasma volume in nephrotic edema is not increased but in some instances is actually reduced.

Nevertheless, there can be no doubt that salt retention is an important factor in the production of edema. For example, the administration of sodium chloride to the patient on the verge of edema precipitates the condition; the edema disappears again upon a salt-free diet. Sodium bicarbonate has a similar effect, while chlorides other than sodium chloride (e.g., KCl, NH_4Cl) either exert no effect or through their acidifying effect (pp. 18 and 388) cause diuresis and the discharge of the edema fluid. It has also been shown by Hastings and Van Dyke that edema can be produced in dogs by the administration of

sodium bromide. These and other facts have suggested that the influence upon the production of edema is exerted by the sodium rather than by the chloride ion.

The retention of salt and water in nephrosis is apparently due to extrarenal factors. It is evident, that since the water and sodium chloride of the blood are not increased the kidney need not be held responsible for their retention in the body. The present day view is that the water and salt are deviated into the tissues and do not reach the kidney for excretion—a conception expressed in the term *pre-renal deviation*. An explanation for the influence of salt in the formation of edema fluid is suggested by the following observations upon normal persons. (a) When sodium chloride is given in excess it does not immediately appear in the urine, there being a lag of three days or so in its excretion. (b) It has been shown by Padtberg that the skin and subcutaneous tissues store the ingested chloride. (c) Veil found that when a large amount of sodium chloride was given, a rise in blood sodium chloride and a great increase in blood water first occurred. Later, the water and salt were poured into the tissues, and the composition of the blood returned to normal. Finally, the salt was excreted, though no apparent change in the blood chloride occurred. (d) Edema may be produced in healthy persons by the administration of very large quantities of salt followed by the drinking of an abundance of water. Baird and Haldane took sodium chloride (38 grams) or sodium chloride and bicarbonate in 500 cc. of water. If, while the diuresis which followed the salt ingestion was subsiding, $2\frac{1}{2}$ liters of water were drunk, there was no apparent effect, the urine volume continuing to fall. Edema about the ankles was noted. When, however, an additional 500 cc. were drunk, profuse diuresis resulted. It was also found that water or isotonic saline caused a much greater diuresis than hypertonic saline. They give as the probable explanation of their results that the salt was first deposited as a hypertonic solution in the tissues, the water which was ingested later left the capillaries to produce an isotonic tissue fluid. Water ingested in excess of this requirement was excreted. The smaller diuretic effect, i.e., the greater water retention, of hypertonic saline as compared with that induced by water or hypotonic saline finds a similar explanation. (See also water diuresis, p. 389.)

It is seen, therefore, that even in health the balance between intra- and extra- capillary fluid

can be upset and a temporary edema produced. Normally fluid is forced out of the capillary near the arterial end where the blood pressure overbalances the colloid osmotic pressure (p. 23). At the venous end, where the blood pressure no longer exceeds the pressure of the tissue fluid and the osmotic pressure of the plasma proteins, water is taken up. The fluid poured into the tissues as a result of the deposition of chloride, therefore, soon undergoes reabsorption. When, however, the concentration of plasma protein is low, reabsorption becomes more difficult. The water which has migrated from the vessels to dilute the tissue fluids to isotonicity is not readily removed. Deficit in the plasma protein is therefore the primary cause of nephrotic edema; salt retention in the tissues is a contributory factor; salt, like water itself plays a passive rôle simply enabling more isotonic tissue fluid to be formed i.e., providing

TABLE 31

Rate of excretion of casts, blood and epithelial cells
per twelve hour period
(After Addis)

	AVERAGE	LOWEST	HIGHEST
Casts.....	1,040	0	4,270
Red blood cells.....	65,750	0	425,000
White blood and epithelial cells.....	322,500	32,400	1,835,000

one of the essential constituents of the edema fluid. In other words, water can only be retained as an isotonic fluid; if, therefore, salt is withheld the excess water is excreted. It is also recognized that in certain dehydrated states ingested water is not retained unless salt is also supplied.

In *acute nephritis*, especially in the earlier stages, edema may occur in the absence of plasma protein deficit. The edema is not widespread as a rule, but may appear before the renal manifestations. It is considered as due to increased permeability of the capillary wall; the high protein content of the edema fluid (1 per cent) supports this conclusion. It is likely that the toxic substance which has produced the inflammatory lesions in the glomerular capillaries has also injured the systemic vessels. It is significant that poisons, such as the toxins of diphtheria and scarlet fever, and other substances which cause glomerular damage, are also general capillary poisons.

IV. CASTS

Part of the protein material which has passed through the glomerulus may become moulded in the tubules to

form the microscopical urinary bodies known as casts. Blood which has exuded from the glomeruli, epithelial cells shed from the tubules, or lipoid material, may become moulded in a similar way. The several varieties of casts—*blood*, *epithelial*, *fatty* or *waxy*—are named according to the material of which they are composed. *Hyaline* casts are formed of coagulated albumin and are translucent and homogeneous. *Granular* casts are made of a conglomerate of blood or epithelial cells in a matrix of albumin. In the terminal stages of renal failure the shed epithelial cells of the larger collecting tubules form exceptionally large elements termed *renal failure casts* (Addis). The urine may also contain many free red and white cells, the numbers varying according to the type and severity of the kidney lesion. Nevertheless, the presence in the urine of relatively small numbers of hyaline casts or even of a few blood cells is by no means an indication of renal disease. Addis examined the urine of 74 healthy medical students and found hyaline casts in 45. The figures for the rates of excretion for the entire group are given in table 31.

V. POLYURIA AND OLIGURIA

An increase in the volume of the night urine—*nycturia*⁴ (p. 396)—is often one of the first indications of chronic renal disease, and polyuria during day and night is characteristic of the earlier stages of chronic glomerulo-nephritis. Unlike that of diabetes insipidus, the polyuria of kidney disease does not respond to pituitrin. Nycturia is usually defined as the passage during the night period of over 500 cc. of urine having a specific gravity of less than 1.018. It is looked upon as the effort of an inefficient kidney to catch up with the work of excreting urea and other low threshold substances which it has been unable to accomplish during the day. In the later stages of renal insufficiency the output of urine during the 24 hours is reduced considerably below the normal—*oliguria*.

The polyuria of chronic nephritis is usually considered to be a compensatory response of the kidney to the reduction in the number of functioning renal units. Certain experimental observations seem to support this conception.

Rose Bradford found that when a part—sometimes as small as one-eighth or one-fourth—of the renal substance of an animal was excised the remaining tissue responded within 24 hours by excreting large quantities of very dilute urine. The polyuria persisted through-

⁴ This applies, of course, only under ordinary conditions of fluid intake. A healthy person may have to get up in the night to pass urine if he has drunk much fluid before retiring.

out the period of observation, which extended over a period of from 1 to 2 years. When the amount of excised renal tissue was small, urea retention did not result. Verney and his associates carried out similar experiments upon isolated kidneys perfused by means of a heart-lung preparation. When a primary branch of the renal artery of one kidney was ligated 50 per cent of its tissue was put out of action. Nevertheless, though the blood flow was reduced by one-half, there was no reduction in the quantity of urine formed by this kidney. It produced as much urine as the sound kidney of the opposite side. In other words, the active kidney tissue which remained, immediately doubled its output and compensated fully for the functionless portion. The urine flow gradually increased throughout the experiment until finally it was some 30 times greater than that of the sound kidney. The composition of the urine from the injured kidney was altered. The urea percentage as well as the total quantity excreted showed a profound fall. It appears, however, that per unit of functioning tissue, the affected kidney excreted slightly more urea than the normal one. The chloride percentage was unchanged, so that the absolute amount, i.e., the amount per unit of time, excreted by the functioning half of the kidney was much greater (4 times in one experiment) than that excreted by the kidney before ligation, or than that excreted by the kidney of the opposite side. The specific gravity of the urine approached that of deproteinized plasma. In brief, the injured kidney excreted much more water and chloride and much less urea than the normal organ. The results of these experiments resemble closely those of chronic nephritis.

The polyuria in the foregoing experiments has been ascribed to the greater quantity of filtrate formed as the result of adaptive vascular changes within the kidney. The latter are probably brought about through a local nervous mechanism but the possibility of an intrarenal hormonal factor being concerned must also be considered. The juxta-glomerular apparatus (p. 379) is the most likely structure through which the control of the intrarenal circulation is effected. Another factor in the augmentation of the urine flow in Verney's experiments is, as pointed out by Winton, the reduction in intrarenal pressure (p. 382) resulting from the diminished blood supply. In other words, the kidney shrinks within its capsule, the pressure of the renal tissue upon the tubules being thus relieved and the effective filtration pressure increased. The polyuria of chronic nephritis also is probably due in part to an increased filtration brought about in the following ways. (a) By changes in the relative calibers of the afferent and efferent vessels (p. 387). (b) By a rise in general blood pressure (see p. 381).

This is a variable and apparently a non-essential factor, for polyuria may be present without any rise in systemic blood pressure and we have just seen that it occurs in the isolated kidney. (c) The reduction in the plasma osmotic pressure resulting from protein deficit will also serve to augment the *effective* filtration pressure. The absence of a rise in blood pressure in some cases of chronic nephritis with polyuria may find an explanation in the fact that the plasma osmotic pressure has been greatly reduced (p. 381).

The polyuria of nephritis, however, is not largely, at any rate, a compensatory response, but is also largely due to tubular impairment. It can readily be understood how failure of tubular function would, through diminishing re-absorption, increase the urine volume, even though the glomerular filtrate were of normal composition. But when the filtrate has a high urea content and consequently a higher osmotic pressure than normal, the damaged tubules, in order to absorb the same quantity of fluid (p. 388), would actually be required to perform more work than in health. Even in the experiments on the isolated kidney, the fact that the quantity of urea excreted by the reduced kidney was, per unit of functioning tissue, only slightly increased, while the entire quantity excreted by this kidney was greatly diminished, indicates that little benefit actually resulted from the polyuria.

It has already been mentioned (p. 402) that polyuria is no indication that the kidney's ability to excrete water is not greatly impaired, for the increased urine volume may almost correspond to the maximum diuresis of which the kidney is capable.

It should also be pointed out that impairment of re-absorption will, paradoxical as it may seem, finally lead to a reduction in urine volume through its unfavorable effect upon filtration, for failure in the re-absorption of fluid from the tubules raises the pressure within Bowman's capsule and so opposes the pressure of blood within the capillary loops (p. 388). This effect may for a time be countered by issuing further calls upon the vascular mechanisms, already mentioned, to increase the intraglomerular pressure. The progressive destruction of the capillary loops, by reducing the extent of the filtering surface, is of course also a factor in causing the oliguria which occurs in the later stages of the disease. Another possible factor should not be lost sight of, namely, the greater back diffusion which, as Richards

(p. 384) has shown, occurs when the tubular membrane is severely damaged.

VI. UREMIA

Two types of uremia are recognized—*true uremia* and *false or eclamptic uremia*.

True uremia is the terminal manifestation of renal failure. Its chief features are muscular weakness, dyspnea, mental disturbances, increased tendon jerks, nausea and vomiting, muscular twitchings, stupor and finally coma with periodic breathing. The excretion of a small volume of urine of low specific gravity (around 1.010), a high degree of urea retention (150 to 500 mg. or more per 100 cc.) and a low blood urea clearance (below 10 per cent of the normal) precede the uremic state.

Though the symptoms are associated with a high degree of nitrogen retention, none of the known nitrogenous wastes, urea, uric acid or creatinine, is responsible. None of these is toxic in relatively large doses; uremia is not produced when animals are fed these substances and their concentrations in the blood raised well above the limits found in renal insufficiency. Bollman and Mann, experimenting upon dogs, implanted the ureters into the intestine. The continued reabsorption of urine caused a rise in the blood urea nitrogen to over 800 mg. per cent yet no toxic symptoms resulted.

The manifestations of uremia are divisible into two groups, namely, those of *depression*, e.g., apathy, muscular weakness, stupor and coma, and those indicative of *neuromuscular hyperexcitability*, e.g., increased tendon jerks, muscular twitchings or jerkings and other irritative phenomena. Sometimes one type of symptom predominates, sometimes the other. The diverse nature of the manifestations strongly suggests that they are due not to a single retention product but perhaps to several. Becker's studies provide important evidence for the view that the signs of depression are due to the absorption of putrefactive products, especially phenols, from the intestinal tract. The hepatic functions are defective in the uremic state and failure of the detoxicating function of the liver (p. 507) combined with renal insufficiency will permit the accumulation in the circulation of free phenols, as well as of the less toxic conjugated compounds. Becker's observation that phenolic bodies are increased in the blood in uremia has been confirmed by Mason and his associates. Among the most important observa-

tions which can be cited in support of Becker's conception are that symptoms of chronic phenol intoxication closely resemble those of uremia; that the introduction of aromatic amino-acids into the rectum of a uremic patient increases severity of the symptoms. Furthermore, onset of the uremic manifestations coincides with the appearance of phenols in the cerebrospinal fluid.

The most probable cause of the increased neuromuscular excitability is a reduction in concentration of ionized calcium (p. 704) in body fluids and tissues, which is most likely in turn the result of phosphate retention. It is possible on the other hand, that an increase in organic metabolites such as citrate or oxalate may also result in the depression of the ionized calcium. There is some evidence that the irritative phenomena are in part due to guanidine intoxication. It will be recalled that the guanidine nucleus contained in the creatinine molecule and that creatinine retention is a prominent feature of chronic nephritis.

False or eclamptic uremia is characterized by epileptiform convulsions which are due, apparently, to cerebral edema. This type may occur in the absence of renal insufficiency (as in nephroses), indeed, it may occur in the absence of renal disease. It is occasionally seen in angioneurotic edema (p. 32) which supports the belief in its being due to cerebral edema. Other signs of increased intracranial pressure, e.g., severe headache, vomiting, slow pulse, hypertension and sometimes choked optic discs, are present. Volhard regards cerebral edema as due in many instances to intracranial circulatory disturbances—arteriolar constriction with consequent asphyxia and increased permeability of the walls of the cerebral capillaries.

A type of false uremia resembling the foregoing in several respects occurs in arterial hypertension. It is thought to be due to intracranial vascular disturbances alone, i.e., without cerebral edema. Epileptiform convulsions, headache, vertigo, homonymous hemianopia, hallucinations, aphasia, temporary paralysis, paroxysmal attacks of dyspnea, or even Cheyne-Stokes breathing, may occur. *Periodic encephalopathy* is a term sometimes employed in referring to this condition.

VII. ACIDOSIS

Acidosis is frequently present in the later stages of chronic glomerulonephritis. This is not surprising, since the insufficiency of the kid-

involves all its functions, and one of the most important of these is the regulation of the acid-base balance of the plasma. The fall in the ammonia/acid ratio found in nephritic conditions (p. 393) indicates a reduction in ammonia production. Acids must then be excreted to a greater extent in combination with fixed base which is therefore lost to the body. The conversion of the alkaline phosphate to the acid salt occurs in the distal tubules, and it is not improbable that impairment of this function is also responsible for a loss of base. Peters and his associates have found a reduction in bicarbonate reserve in a large proportion of non-edematous nephritic cases. The diminished alkali reserve was found to be chiefly due to reduction in total base. Contributory causes were the accumulation of phosphates and sulphates and, when carbohydrate of the diet was deficient, of ketones.

VIII. ARTERIAL HYPERTENSION (SEE P. 128)

MICTURITION

Outline of the anatomy of the urinary tract

The muscular coat of the *ureter* is arranged in three layers, an *external longitudinal*, a *middle circular* and an *internal longitudinal*.

The muscle of the *urinary bladder* is also disposed in three layers, an *external*, a *middle* and an *internal*. The fibers of the external layer run longitudinally, that is, in the long axis of the bladder. The fibers of the middle layer are thinly scattered; they have a circular arrangement and run both transversely and obliquely to the long axis of the viscus. The fibers of the internal layer follow a reticular pattern but for the most part run longitudinally.

The vesical mucous membrane is separated from the internal muscular layer by a submucous coat of loose areolar tissue. The mucosa is thin and, when the bladder is empty or contains only a small quantity of urine, has a corrugated appearance due to the presence of numerous folds or *rugae*. The latter disappear when the bladder becomes distended by the accumulation of urine. The vesical epithelium as well as that lining the ureter is of the type called transitional. The mucosa of the empty bladder shows several layers of cells; those of the deepest layer are cuboidal or even columnar in shape; the most superficial layer consists of broad cells with a convex free surface. In the mucosa of the distended bladder only two cell layers are evident, a deep stratum of cuboidal and a superficial one of large squamous cells.

The *peritoneum* covers the superior surface of the bladder only.

The ureters pierce the wall of the fundus (or base) of the bladder very obliquely. From a half to three

quarters of an inch of their lower ends are embedded in the vesical muscle. During contraction of the wall of the bladder these portions of the ureters are compressed by the muscle fibers, thus preventing the reflux of urine as the intravesical pressure rises. The urethral orifice which is situated at the most dependent part of the bladder is guarded by the *vesical sphincter* (*internal sphincter*). This is formed by the condensation of the muscle fibers of the circular layer. The triangular area marked out by the urethral orifice and the two ureteral orifices is called the *trigone* (*trigonum vesicae*). The muscle of the bladder wall is referred to as the *detrusor urinae*. The male urethra is embraced in its membranous portion by the *sphincter urethrae membranaceus*, a striated muscle which is frequently referred to as the *external sphincter*. The *bulbocavernosus* muscle, which is applied to the urethral bulb and surrounds the corpora cavernosa penis, also exerts a constrictor action upon the urethra. The urethral wall itself contains two layers of smooth muscle, an outer circular and an inner longitudinal; in women (who do not possess an external sphincter of striated muscle) this serves to prevent the escape of urine after paralysis of the internal sphincter. The epithelial lining of the urethra is of the columnar type except near the bladder where it is of the transitional variety, and a short distance from the external urethral orifice where it is stratified and squamous.

FILLING OF THE BLADDER

The ureters exhibit rhythmical peristaltic contractions which travel at a speed of from 20 to 25 mm. per second (rabbit) and at a frequency from 1 to 5 per minute, according to the volume of urine formed by the kidney. The peristaltic waves serve to propel the urine from the pelvis of the kidney to the bladder. The urine therefore enters the bladder not in a continuous stream but in separate squirts synchronous with the arrival of the peristaltic waves.

The detrusor muscle exhibits two types of activity, a sustained contraction or tonus, and intermittent contractions.

The bladder, in common with other hollow viscera, is capable of adjusting its tone and so of adapting its capacity to changes in the volume of its contents with relatively little alteration in internal pressure. It thus differs in its behavior from an elastic hollow sphere composed of a non-living material. For example, when a moderate quantity of fluid is run into the bladder through a catheter the intravesical pressure shows a transient rise, due to the tonic resistance offered by the bladder wall, but then declines again to near its previous level as adaptation occurs. As successive volumes of fluid are introduced the

curve of intravesical pressure therefore shows a gradual step-like ascent until the bladder contents are unusually large. From then on further additions of fluid cause a much more abrupt rise in pressure. The adaptation is not to a constant pressure (15 cm. of water), as was previously taught, but is always to a pressure a little higher than that existing before the fluid was introduced. In the experiments of Denny-Brown and Robertson upon normal human subjects fluid was run into the bladder 50 cc. at a time. An increase in volume of the contents of the bladder from 50 cc. to 400 cc. caused little change in pressure (fig. 179). When completely paralyzed (as during the first two or three weeks following a transverse lesion of the cord) the bladder does not behave in this way, but simply as an inert elastic bag showing no tendency to respond to an increase in tension upon its walls or to adapt itself to its contents (Holmes); when successive quantities of fluid are introduced the curve of intravesical pressure rises along a perfectly smooth line.

Tension is the adequate stimulus for the sensory end organs in the bladder wall. When therefore the bladder becomes distended by the accumulation of urine and the intravesical pressure reaches a certain value, rhythmical contractions of the detrusor muscle are set up. As the pressure rises further these culminate in the movements constituting the micturition reflex, namely, a strong contraction of the detrusor muscle accompanied by relaxation of the internal sphincter, and followed by opening of the external sphincter. It is usually stated that the reflex occurs at an intravesical pressure of from 15 to 18 cm. of water, but it may be activated by a pressure considerably lower than this. The urine is expelled with considerable force, the pressure within the bladder rising during the contraction of the detrusor to around 130 cm. of water. Since adaptation requires a certain time to take place, the reflex is activated at a lower urine volume than usual if the accumulation of urine is rapid. At the average rate at which urine forms micturition occurs, unless restrained, after from 250 to 300 cc. have collected.

THE VOLUNTARY CONTROL OF MICTURITION

The act of micturition though essentially reflex in nature is usually initiated by an effort of the will; it also can be voluntarily inhibited or be interrupted at any stage. The desire to urinate is accompanied by a vague feeling in the penis or perineum. The sensation appears when the urine

volume is from 200 to 300 cc. If the act is long postponed a feeling of fullness and discomfort culminating in pain results. It is only in the infant or when, as a result of disease, the bladder is isolated from the control of the higher nervous centers, that micturition is a purely reflex act. Under ordinary circumstances in the adult, when the desire to micturate arises, the act is restrained until an opportunity for emptying the bladder presents itself. The restraint is then lifted and the reflex occurs automatically.

The voluntary restraint exerted upon micturition consists, according to Denny-Brown and Robertson, of inhibition of the detrusor with contraction of the external sphincter and perineal muscles. No evidence was obtained by these observers that the internal sphincter was under direct voluntary control, though a reciprocal increase in tone of the sphincter muscle accompanies inhibition of the detrusor. It was found that at a certain urine volume, contractions of the bladder and a consequent rise in intravesical pressure could be readily induced by an effort of the will; contraction of the abdominal muscles was not necessarily associated with the performance of the act. The removal of restraint and the voluntary facilitation of the spontaneous bladder contractions are considered to be the important factors. At low urine volumes restraint is apparently exercised subconsciously. These observers therefore regard the act of micturition as being normally controlled through variations in voluntary and subconscious restraint of the reflex mechanism. Micturition therefore presents a very unusual feature in that movements innervated by autonomic nerves can be controlled by voluntary impulses.

Though the abdominal muscles play a non-essential part in micturition, the act, under ordinary circumstances, is started by the contraction of these muscles; and it is well known that the bladder can be emptied though it contains only a few cubic centimeters of urine. The flow of urine is also accelerated during micturition by the rise in intraabdominal pressure induced by the voluntary contraction of the abdominal muscles. Relaxation of the muscles of the perineum occurs as an associated movement at the commencement of micturition; the significance of this movement is obscure. After the bladder has been emptied the bulbocavernosus muscle (ejaculator urinae) contracts and expels urine which had been left in the urethra.

THE REFLEX MECHANISMS OF MICTURITION

Barrington describes six integrated reflexes as constituting the act of micturition in the cat, namely:

(1) *Contraction of the detrusor* evoked by distending the bladder; the afferent and efferent limbs of this reflex are in the pelvic nerves, its center in the hind-brain. Contraction of the detrusor is accompanied by reciprocal relaxation of the internal sphincter.

(2) *Contraction of the detrusor* caused by running fluid through the urethra. The afferent pathway for this reflex is in the pudendal (pudic) nerves, its efferent in the pelvic nerves and its center in the hind-brain. Through this reflex the contraction of the detrusor caused by the first reflex is sustained until the bladder is completely emptied.

FIG. 179. Curve of pressure changes in the human bladder during filling (upper curve) and emptying (lower curve). (After Denny-Brown and Robertson.)

(3) *Contraction of the detrusor* (transient and weak) when the proximal portion of the urethra is distended. The hypogastric nerves contain both afferent and efferent paths for this reflex; its center is in the sacral part of the cord.

(4) *Relaxation of the external sphincter* when fluid passes along the urethra. Afferent and efferent fibers are in the pudendal (pudic) nerves, the center is in the sacral part of the cord.

(5) *Relaxation of the external sphincter* when the bladder is distended. The afferent path is in the pelvic, the efferent in the pudendal nerves, its center in the sacral part of the cord.

(6) *Relaxation of the plain muscle in the proximal third of the urethra* caused by distending the bladder. Both afferent and efferent paths of the reflex are in the pelvic nerves; its center is in the sacral part of the cord.

In the normal act of micturition the first of these reflexes, namely, contraction of the detrusor in response to distention of the bladder, brings the

others, with the exception of the third automatically into action. It is questionable whether the third reflex is called into play under ordinary circumstances.

THE INNERVATION OF THE URINARY TRACT

The *ureters* in their upper part receive sympathetic fibers from the renal plexus, in their middle part from the spermatic (or ovarian) plexus and near the bladder from the hypogastric nerves. The sympathetic fibers to the ureters exert a predominantly motor effect, though it appears that inhibitory fibers are also derived from the sympathetic. It is thought by some that the

FIG. 180. To show innervation of the bladder. (After Learmonth.)

ureter receives fibers from the parasympathetic as well, since certain parasympathomimetic drugs cause motor effects. The existence of a parasympathetic innervation has not been demonstrated anatomically.

The *efferent nerves to the bladder* are the sympathetic and parasympathetic. The *sympathetic* furnishes inhibitory fibers to the detrusor muscle, and motor fibers to the trigone, internal sphincter and the smooth muscle of the proximal part of the urethra.⁵ These fibers arise from the lumbar

⁵ The sympathetic also causes contraction of the urethral orifices and of the muscle of the seminal vesicles, ejaculatory ducts and prostate.

spinal segments and pass through the inferior mesenteric plexus, the superior hypogastric plexus (presacral nerve) and the inferior hypogastric plexus to reach the hypogastric ganglion (fig. 180). Postganglionic fibers, which probably have their origins in the latter ganglion, enter into the formation of the vesical plexus; this lies in relation to the fundus of the bladder (the hypogastrics in some species apparently contain motor as well as inhibitory fibers).

The *parasympathetic* supplies motor fibers to the detrusor muscle (which govern the tonus and contractile mechanisms) and inhibitory fibers to the internal sphincter. The sympathetic and parasympathetic nerves are therefore reciprocal in their actions. The parasympathetic fibers arise from the second and third sacral spinal segments and to some extent from the first and fourth. They are conveyed in the pelvic (see also p. 942) nerves (*nervi erigentes*) to connect with ganglion cells lying in close relation to the bladder wall. According to Henderson and Roepke, the tonus mechanism is cholinergic (p. 948) but not the phasic contractions.

Both sets of autonomic nerves apparently exert a constant influence upon the tone of the detrusor and internal sphincter; the effect of one set being balanced against the other. Section of the sympathetic or parasympathetic causes, respectively, an increase or decrease in tone of the sphincter. In paresis of the bladder due to injury of the parasympathetic innervation, excision of the presacral nerve is sometimes performed with the object of removing the inhibitory influence of the sympathetic and thus enhancing the action of the pelvic nerves. Voluntary control of the detrusor is exerted apparently through the pelvic nerves.

The striated muscle constituting the external sphincter is innervated through the pudendal (pudic) nerves.

The *afferent* paths from the bladder travel in both pelvic and hypogastric nerves, those from the urethra in the pudendal nerves. The afferent fibers essential for the reflex movements of the bladder are contained in the pelvic nerves, those for the movements of the urethra in the pudendals. The hypogastric nerves contain no afferents for any of the important reflex mechanisms. The sensations set up by distension of the bladder are conveyed in both the pelvic and hypogastric nerves. The sensation of pain travels chiefly in the hypogastrics, but also in the pelvic nerves. Excision of the presacral nerve is practised for the

relief of vesical pain. Tactile and thermal sensations are conveyed from the bladder mainly in the pelvic nerves (Learmonth).

THE NERVE CENTERS GOVERNING MICTURITION

Centers for micturition are situated in the mid-brain, hind-brain and spinal cord. The observations cited on page 412 upon the voluntary control of the detrusor muscle also indicate the existence of a center at the cortical level, and electrical excitation of the premotor area causes a rise in vesicle pressure followed by micturition. Increase in the tone of the bladder wall follows electrical stimulation of the anterior hypothalamic nuclei; stimulation of the posterior nuclei causes inhibition (Beatty and Kerr).

Barrington, experimenting with cats, found that destruction of a small area of the hind brain (lying ventral to the internal edge of the superior cerebellar peduncle and extending forward from the level of the motor nucleus of the fifth nerve to the anterior end of the hind-brain) temporarily abolished the animal's ability to empty its bladder voluntarily. Destruction of an area in the mid-brain, extending from the ventral part of the posterior end of the cerebral aqueduct to just beyond the mesencephalic root of the fifth nerve, was followed by permanent loss of voluntary micturition.

The reflex performance of the act was not, however, impaired. A more extensive lesion in the region of the mesencephalic root caused, in addition, frequency of micturition. Levin and Longworth observed that, in cats, injury to the tegmentum of the mid-brain was followed immediately by hyperactivity of the detrusor muscle to stretch. The capacity of the bladder becomes reduced as a consequence and rhythmic waves of contraction appear. After a time, this increased activity diminishes and the bladder enlarges again.

The spinal centers lie in the second, third and fourth sacral segments. Only the third, fourth, fifth and sixth reflexes described on page 413 are carried out through the spinal centers.

The descending and ascending paths conveying impulses to and from the spinal centers of micturition are situated in the dorsal half of the lateral column of the cord near its periphery, i.e., in close proximity to the pyramidal tract. The fibers of these paths show extensive crossing in the sacral segments (Barrington).

THE EFFECTS OF NERVE SECTION AND OF CORD INJURIES UPON MICTURITION

Section of the hypogastric nerves does not interfere with micturition; these nerves contain neither efferent

nor afferent fibers essential for the performance of the act. Incontinence which might be expected to result (since motor fibers are conveyed by this nerve to the internal sphincter) does not occur. Indeed, incontinence does not follow a prostatectomy operation involving destruction of the internal sphincter, for the external sphincter is capable alone of preventing the escape of urine. Frequency of micturition was found by Barrington to follow section of the hypogastrics in the cat; it also occurs as a temporary effect of resection of the presacral nerve in the human subject. The phenomenon is due, apparently, to the loss of the inhibitory action of the sympathetic upon the tone of the detrusor and the impairment of the ability of the bladder to adapt its capacity to as large a volume of urine as usual.

Section of the pudendal nerves in the human subject is also, according to Learmonth, without any notable effect upon micturition, though of course paralysis of the external sphincter results.

Section of the pelvics causes paralysis of the bladder wall. The detrusor is atonic; the tone of the internal sphincter is raised. Retention of urine with overdistension of the bladder and overflow—dribbling—occurs. Barrington found that the tone of the sphincter diminished after a few days and the animal, apparently experiencing the sensation of fullness of the bladder, assumed the usual position for micturition and performed the act by a contraction of its abdominal muscles.

Severance of the posterior sacral nerve roots is followed immediately by the loss of all the important reflexes of micturition since the afferent paths (through the pelvics and pudendals) are interrupted; the bladder wall is flaccid and the resistance at the internal sphincter is increased. However, after a period of overdistension with overflow, the bladder empties itself automatically at intervals. The sensations of vesical distension (afferent fibers of hypogastrics intact) are retained.

Destruction of the sacral nerves (as in lesions of the cauda equina) or of the spinal centers will interrupt not only motor impulses to the bladder, but also the afferent impulses travelling by the pelvics and pudendals. The bladder is then completely isolated from central nervous control; but, after a period of retention of urine with overflow it expels its contents automatically. The detrusor and internal sphincter act coöordinately. Such an action suggests a neural mechanism of some sort. It occurs in animals even after the hypogastrics have been sectioned as well, and time allowed for degeneration to occur; it cannot therefore be due to preganglionic axon reflexes. Probably, in such and other instances in which motor impulses from the central nervous system have been interrupted, local reflex arcs through ganglion cells in the vesical plexus or bladder wall are responsible for the automatic action. The latter is only a makeshift for the normal micturition reflex since the bladder is not completely emptied but always retains a part of its contents (residual urine).

After transection of the cord above the sacral region, normal micturition cannot occur. Nevertheless, after a variable period of retention with overflow the spinal centers assume control and the bladder empties at intervals automatically (see also mass reflex, p. 1470). Owing to the absence of the first and second reflexes of Barrington which, as just mentioned, are governed by higher centers, the bladder does not empty itself completely, but always contains a quantity of residual urine.

Bladder sensibility is completely lost following section of the hypogastrics and pelvic nerves or transection of the cord above the entrance of the afferent fibers of the hypogastrics. Injury or disease (e.g., tabes) of the posterior columns involving these fibers together with those from the sacral roots will have a similar effect.

SECTION V. DIGESTION

CHAPTER XXXVIII

THE SALIVARY GLANDS AND THE SECRETION OF SALIVA

General description and structure of the glands

Saliva is secreted mainly by three paired masses of cells—the *submaxillary*, *sublingual* and *parotid glands*. There are also small glands scattered over the buccal mucous membrane, which secrete a mucoid fluid. The cells of the glandular tissue are aggregated into a great number of small groups, the individuals of which are arranged in a single layer around a small central cavity or alveolus. The cells are more or less wedge-shaped with their apices converging toward the central cavity and their bases directed outwards. The cells pour their secretion into the alveolus from which a fine duct drains the secretion away. Ducts from neighboring alveoli join to form ducts of larger caliber which unite again to form still larger trunks, until finally through a succession of junctions and the formation of channels of ever increasing size, the secretion is emptied into the mouth by a single large duct, in the case of the submaxillary and parotid glands, or by several of medium size, in the case of the sublingual. The general arrangement of the ducts reminds one of the stem branchings of a bunch of grapes—the rounded alveoli at the ends of the finest channels corresponding to the grapes. Glands showing such a pattern are, therefore, termed *racemose*.

There are two types of salivary cells—*serous* and *mucous*. The alveoli of the *parotid gland* are composed entirely of one type—the serous. This type of cell secretes a thin watery fluid. The *submaxillary gland*, on the other hand, in man, is of the mixed type, some of its alveoli are composed entirely, like the parotid, of serous cells, while others contain only cells of the mucous type. The two varieties of alveoli are indiscriminately intermingled with one another, either singly or in clusters. The mucous cells secrete a thick, viscid juice rich in mucin. In the *sublingual*, the alveoli are predominantly of the mucous type though a few serous alveoli may also be seen. In both the submaxillary and sublingual glands, particularly the former, the two types of cells may also be found in a single alveolus. The serous cells then appear as crescent-shaped elements—*demilunes*—pressed against the periphery of the alveolus between the limiting membrane and the larger, more numerous mucous elements (fig. 181).

The *parotid secretion*, as naturally follows from the character of its cells, is thin and watery in nature; it has a low content of organic material. It is delivered into the mouth through the *duct of Stensen*, which

opens upon the inner surface of the cheek opposite the second molar tooth. The duct of the submaxillary—*duct of Wharton*—runs from the substance of the gland which lies under shelter of the mandible, and opens upon the floor of the mouth to one side of the frenum of the tongue. The secretory ducts of the sublingual—the *ducts of Rivinus*—are several fine tubes which open beside the frenum. The secretion from the submaxillary gland may be either thin and watery (serous) or thick and viscid (mucous), the character at any time depending, as shall be shown later, upon the nature of the secretory stimulus. The *sublingual secretion* on account of its scarcity in serous cells is usually of the mucous type.

MINUTE APPEARANCE OF THE SECRETORY CELLS. The cytoplasm of either the serous or mucous cell is not homogeneous but shows a granular structure, due to the presence of minute colloidal droplets. The granular appearance is different in the two cell types. In the case of the serous cells they are fine, and when the gland is in the resting state, load the cytoplasm to such an extent that the nucleus is almost obscured. These droplets are believed to furnish the enzyme of the secretion, and are consequently termed *zymogen granules*. In the case of the mucous cells coarser *mucinogen granules* are seen. From these are derived the mucin which gives to the secretion of these cells its slimy character. When the glands enter upon secretory activity, the granules—whether zymogen or mucinogen—become less numerous as a result of their extrusion into the alveolus. After a prolonged period of secretion only a few remain in the region of the cell bordering the cavity of the alveolus, the rest having been discharged along with the water and other constituents of the juice. After a period of rest they accumulate again and gradually fill the cell.

THE CONTROL OF SALIVARY SECRETION

Two methods are at the body's disposal for the control of secretion. Glandular cells, in general, may be excited either through the mediation of nerves or chemically by the action of hormone (p. 670). When a quick response is required the nervous type of control is utilized. On the other hand, when rapidity of response is not a necessity, hormone control is employed. It will be seen later that some glands are controlled by both methods. Usually in such instances nerves

impulses initiate the secretion and hormones then maintain it over longer periods. It would appear that nervous energy is economized whenever it is possible for the secretion to be carried out efficiently by hormonal means. In the case of the salivary secretion a rapid response, in man and the carnivora at any rate, is obviously essential, since the food remains for such a short time in the mouth. Nervous mechanisms, therefore, are relied upon to bring about salivary secretion; there is no evidence of a specific hormonal mechanism. The salivary cells, however, are by no

lumar divisions of the autonomic nervous system (p. 938).

The submaxillary and sublingual glands receive their bulbar supply through the *chorda tympani* nerve. These fibers have the following course. Arising from the superior salivary center situated in the medulla in the region of the nucleus of the 7th nerve they leave the brain in the *nervus intermedius of Wrisberg* (p. 859). They pass without interruption through the genicular ganglion of the facial nerve and descend with the facial to the point where its *chorda tympani* branch is given off. They enter this nerve which upon approaching the cavity of the mouth joins the lingual nerve. In the floor of the mouth the secretory fibers leave the lingual again to make connections with the nerve cells of small ganglia. From these, postganglionic fibers arise which terminate by fine arborizations around the

FIG. 181. Human submaxillary gland showing both mucous and serous groups of cells. Inserts are views with oil immersion, zymogen granules are clearly shown. (After Stormont, from Cowdry's *Special Cytology*.)

FIG. 182. Showing distribution of parasympathetic secretory nerves, to cells and blood vessels of submaxillary gland of rabbit. The serous cells are believed to be supplied by the parasympathetic, the mucous cells by the sympathetic. (From Stormont in Cowdry's *Special Cytology*.)

secretory (serous) cells (fig. 182). The ganglia furnishing fibers to the submaxillary gland are small and numerous, and are situated in the hilum of the gland. The sublingual gland contains no ganglion cells, it receives its postganglionic fibers from a small ganglion—the *submaxillary ganglion*—situated in the course of the *chorda* fibers just beyond their point of separation from the lingual and before they enter the gland (see diagram fig. 183).

The sympathetic supply (postganglionic fibers) is derived from the superior cervical ganglion. The fibers reach the gland via the plexuses of the external carotid artery and its branches. The preganglionic fibers arise from the upper one or two thoracic segments of the cord. Fine filaments end in the secretory (mucous) cells.

The *chorda tympani* also carries *dilator* fibers to the blood vessels of the gland; *vasoconstrictor* fibers are derived from the sympathetic.

The bulbar fibers to the *parotid* pursue the first part

Innervation of the salivary glands

The glands are supplied with secretory nerves from two sources—the bulbar and the thoracico-

means unsusceptible to chemical influences, for a number of substances, e.g., drugs and abnormal metabolic products, reaching them through the blood stream are capable of influencing their activity. Even though the salivary glands are under nervous control the immediate excitant of the gland cells is believed to be a chemical substance liberated at the nerve endings (see p. 946).

of their course in the glossopharyngeal, but they follow a devious path before finally terminating around the gland cells. They arise in the medulla from the *inferior salivary* center situated at the upper end of the nucleus of the glossopharyngeal nerve. At the jugular foramen they separate from the glossopharyngeal (petrous ganglion) in its *tympanic branch* (*Jacobson's N.*), and after passing into the trunk of the *small superficial petrosal nerve* are conveyed to the *otic ganglion*. There they communicate with ganglion cells from which postganglionic fibers arise. The

efferent salivary nerves depends upon which of the two types of nerve is chosen for the experiment. If the chorda tympani is stimulated, a profuse watery juice, poor in solids, results, the vessels of the gland dilate and the blood flow through it increases. The oxygen consumption of the gland is increased two- or three-fold. If a manometer be placed in the salivary duct and another in the carotid artery it will be found that when the chorda tympani is stimulated continuously the

FIG. 183. (Diagrammatic.) Shows the innervation of the salivary glands and the course of the nerves of taste (beaded lines). S.S.P., small superficial petrosal nerve, TY.PL., tympanic plexus, TN., tympanic nerve.

latter are transmitted by the *auriculo-temporal* branch of the fifth nerve to the gland cells. The parotid also receives sympathetic fibers. The cell stations of the latter as in the case of the submaxillary and sublingual lie in the superior cervical ganglion. The dilator fibers to the blood vessels travel with the bulbar fibers. The vasoconstrictor fibers are furnished by the sympathetic, and follow the blood vessels into the gland.

EXPERIMENTAL STIMULATION OF THE SECRETORY NERVES

The nature of the secretory response which follows the electrical stimulation of one of the

secretory pressure ultimately rises above the blood pressure. This fact and the increased oxygen consumption of the gland during activity show that the production of saliva is a true secretory process and not simply due to filtration of fluid from the blood stream.

Stimulation of the auriculo-temporal nerve (parasympathetic fibers) to the parotid also causes an abundant watery secretion. Stimulation of the sympathetic fibers to the submaxillary or sublingual gland causes the secretion of small quantities of a thick mucinous saliva. No secretion

follows stimulation of the sympathetic supply to the parotid, though upon microscopical examination of the gland after such stimulation a reduction in the zymogen granules of the cells can be observed, which shows that sympathetic stimulation is not without effect. Stimulation of the cerebral cortex in the dog behind and below the cruciate sulcus causes the secretion of saliva.

THE REFLEX SECRETION OF SALIVA (ARTIFICIAL STIMULATION)

The salivary glands can be readily excited by the artificial stimulation of afferent nerves supplying structures in the mouth. The reflexes are brought about through the salivary centers. The *efferent* limbs of the reflex arcs—the secretory fibers of the chorda tympani and the tympanic branch of the glossopharyngeal respectively—have been considered above. The *afferent* pathways are along fibers contained in the trunks of the chorda tympani and glossopharyngeal nerves, in the lingual, buccinator and palatine branches of the fifth nerve and in the pharyngeal branch of the vagus. The fibers of the chorda tympani subserving the sensation of taste are distributed to the anterior two-thirds of the tongue. They arise from cells in the geniculate ganglion; the central processes of the ganglion cells enter the pons in the *nervus intermedius* of Wrisberg to make connections with cells in the tractus solitarius from which impulses are relayed to the superior salivary nucleus. The afferent fibers of the glossopharyngeal nerve concerned in the salivary reflex, carry sensations of taste from the posterior third of the tongue. They arise from cells in the petrous ganglion. The central processes of these cells enter the medulla to make connections through the tractus solitarius with the inferior salivary center (see also p. 860). The lingual fibers (cells of origin in Gasserian ganglion) furnish the general buccal mucosa with common sensation—touch, pain, etc. Secretion of saliva may be induced by stimulation of the central end of any one of these three groups of afferent fibers. It can also be brought about by stimulating sensory nerves in other situations. For example, experimental stimulation of the central end of the vagus, sciatic or indeed of practically any sensory nerve of the body may cause salivation. According to some, stimulation of afferent nerves of the gastric mucosa is particularly likely to initiate a reflex secretion into the mouth. In

disease, stimuli arising in the esophagus may cause profuse salivation (esophago-salivary reflex).

THE SECRETION OF SALIVA UNDER NATURAL CONDITIONS

In the normal life of the animal the secretion of saliva is brought about reflexly in two ways, either through (1) the stimulation of the nerves of the mouth by the presence therein of food or other substances, or (2) by the stimulation of some organ of special sense other than that of taste. The former type of reflex is termed *unconditioned* or *inherent*, the latter, *conditioned* or *acquired*. A reflex of one type does not, of course, exclude the other, and as a matter of fact both are called into play together under ordinary circumstances.

(1) *The unconditioned salivary reflex*

Materials placed in the mouth call forth after a short latent period (two or three seconds), a secretion of saliva which varies in *quantity* and *quality* with the physical and chemical nature of the substance introduced. The effects which sensations of taste produce upon the secretion of saliva are well known. Among edible substances, those, generally speaking, which are the most palatable or arouse the sensation of taste with the greatest intensity, are the most potent salivary stimulants. Substances that are entirely inedible will, if unpleasant to the taste—strong acids especially—cause profuse salivation. In these instances the secretion depends mainly upon the stimulation of the taste fibers and the stimulus is chemical in nature. But we have seen that stimulation, not only of the taste fibers (chorda tympani and glossopharyngeal) but of the fibers endowing the mucosa of the mouth with common sensibility (lingual nerve) as well will produce a salivary flow. So, materials such as dry sand, inedible powders, whether soluble or insoluble, or any other material which is capable of stimulating these endings in a purely physical way will evoke a secretion. The mere movements of the jaws and of the tongue over the mucosa of the mouth will have such an effect, though there is no material present in the mouth. A secretion occurs when any substance is chewed, whether or not it is edible or possesses taste. The chewing of india rubber (or gum) for instance, the manipulations of the dentist, the contact of his instruments with the oral mucosa or the grinding of a tooth are familiar and potent causes of salivation.

The remarkable *adaptability* or *purposeful character* of the salivary reflex has been remarked upon by Pavlov. The physical and chemical qualities of the juice, as well as its quantity are adapted to the physical or chemical characters possessed by the particular substance initiating the reflex. For instance, if clean pebbles be placed in a dog's mouth, they are expelled—merely allowed to drop out of their own weight. No secretion or very little occurs, since none is required; but if the stones are crushed and given as a powder, a profuse watery salivation follows to rid and cleanse the mouth of the useless material. The juice in this instance is poor in organic material and resembles that obtained upon electrical stimulation of the chorda tympani nerve or of the parasympathetic fibers to the parotid. Acid produces an abundant saliva which, according to Pavlov, is relatively rich in protein; this exerts a buffer action which reduces or annuls the injurious effect of the acid. The salivary response to the various foods is also adapted to their peculiar qualities. A chunk of meat, if given to a dog, is very quickly swallowed. Under the circumstances what is most required of saliva is a lubricant action. Accordingly, a highly viscous juice, rich in mucin is produced. If the meat be first dried and powdered, or if dry biscuit be fed to the animal the secretion is characteristic of parotid or chorda saliva—e.g., watery and abundant, but poor in mucin. Milk provokes a saliva rich in mucin, and foods, in general, produce a saliva rich in organic material—mucin and ferments—while inedible substances tend to call forth a more watery juice. These adaptations are much less pronounced in man.

The conditioned or acquired reflex

The secretion poured into the empty mouth when "the mouth waters" is the result of a conditioned reflex. The stimulus which initiates such a reflex is not applied to the nerves of the mouth but is received by one or other of the organs of special sense, particularly those of sight and smell. A conditioned reflex may also be elicited through the sense of hearing or through sensory impressions arising from stimuli applied to the skin. In brief, a conditioned reflex is one in which the cerebral centers play an essential part, and in which training and experience are the basis for the development of the reflex process. Conditioned reflexes are taken up in detail in Chapter LXX.

THE REACTION, QUANTITY AND COMPOSITION OF SALIVA

Human mixed saliva, according to the investigations of Starr is slightly acid in reaction. In 86 per cent of a large series of normal persons the pH was found to

vary between 6.35 and 6.85. The lowest pH found was 5.75 and the highest 7.05. Salivary reaction is dependent mainly upon the relative concentrations of free and combined CO_2 , that is, upon the ratio $\frac{[\text{H}_2\text{CO}_3]}{[\text{NaHCO}_3]}$.

So, in order that the true pH value be obtained the juice must be collected without loss of CO_2 . The older figures in the literature are too high (7.50 to 8.00) since this precaution was not taken. The hydrogen ion concentration of the saliva was found to vary directly with the CO_2 content of the blood. This means that when the CO_2 tension in the blood is high, more CO_2 finds its way into the salivary secretion to lower its pH, and vice versa. Forced breathing causes a lessened amount of CO_2 in the saliva, and consequently a rise in its pH. On the other hand, conditions associated with a retention of CO_2 in the blood cause increased excretion of the gas in the saliva, and an increase in its acidity. Ingestion of NaHCO_3 , while it reduces the acidity of the urine, increases that of the saliva, since a rise in the CO_2 tension in the blood results.

In man the amount of saliva secreted in 24 hours amounts to from 1000 cc. to 1500 cc. The cow secretes some 60 liters in the same time. Ordinary mixed saliva contains about 99.5 per cent of water and 0.5 per cent total solids. It has a specific gravity between 1.002 and 1.012. Its main constituents are as follows:

- I. *Salts* (approximately 0.2 per cent).
 - Sodium and potassium chloride.
 - Sodium bicarbonate.
 - Acid and alkaline sodium phosphates.
 - Calcium carbonate and calcium phosphate.
 - Potassium sulphocyanate.
- II. *Gases*.
 - Carbon dioxide, oxygen and nitrogen.
- III. *Organic substances*.
 - Ptyalin (salivary amylase) and maltase.
 - Serum albumin and globulin.
 - Urea, uric acid and creatine.
 - Mucin, mainly in the submaxillary and sublingual secretions.
 - Vitamin C.

The *bicarbonate* and to some extent the *phosphates* act as "buffers." The *chlorides* are necessary for the activation of the amylase. The *calcium salts* which are soluble in acid but insoluble in alkaline media tend to be thrown out of solution when the pH rises. The carbonate and phosphate of calcium may be deposited in the form of concretions (*salivary calculi*) within the ducts or, in combination with organic material, may be laid down upon the teeth as "tartar." A high salivary pH and a juice rich in mucin are believed to be conducive to tartar deposition and the development of calculi. The *potassium sulphocyanate* (KSCN) is an excretory product and is probably formed within the body from CN radicles derived from the metabolism of protein. Its production and excretion are thought to represent a detoxicating mechanism. It is said to be in

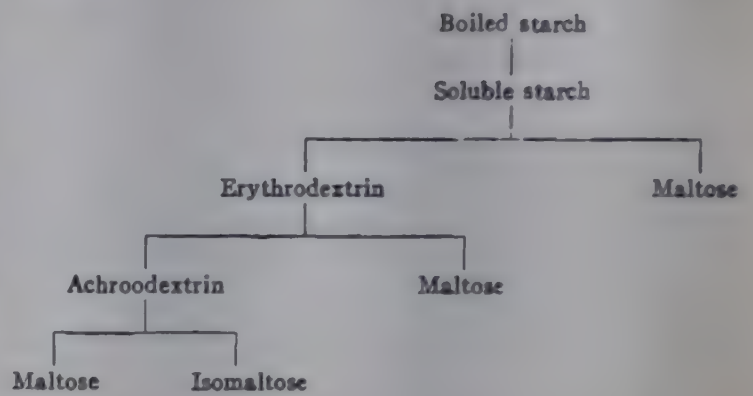

excess in the saliva of habitual smokers, and has been shown by Sullivan and Dawson to be noticeably reduced during the course of pellagra, but returns to normal value during convalescence from this disease.

FUNCTIONS OF SALIVA

(1) **DIGESTIVE.** The starch molecule is acted upon by the ptyalin and split into smaller molecules of the disaccharide maltose. The rapid passage of the food through the mouth precludes the possibility that it is acted upon here by the saliva to any important extent. Whether starchy food after its thorough impregnation with saliva undergoes any significant degree of digestion in the stomach has been debated. The salivary amylase requires for its activity an alkaline, neutral or but faintly acid medium. It was, therefore, thought that the highly acid gastric juice would prevent or soon terminate salivary digestion. It has been shown, however, that the latter part of the meal, which usually contains the carbohydrate, may remain in the fundus of the stomach protected for some time from the acidifying action of the gastric juice by a layer of food ingested previously. For this reason, it is likely that under favorable circumstances considerable digestion of starch is accomplished during this period. Bergeim found indeed, that 76 per cent of the starch of mashed potatoes was transformed into maltose in the human stomach.

If boiled starch be placed in a test tube with mixed human saliva and kept at body temperature, a slow conversion of the starch into maltose takes place. The chemical change occurs in a series of stages which may be distinguished by the manner in which the product of each reacts with iodine. Iodine gives a characteristic blue color with boiled starch. A short time after the saliva has commenced to act a physical change may be seen to have occurred in the starch. It loses its opalescent appearance and becomes *soluble*, though it still gives the blue color with iodine. After a short time the starch becomes partially broken down and converted into a dextrin which now gives a red color with iodine, and on this account is known as *erythrodextrin*. Small amounts of maltose may also be detected. Still later, no color reaction occurs upon the addition of iodine, a colorless dextrin—*achroodextrin*—has been formed. Finally the starch is entirely converted into maltose and isomaltose. In the final stage traces of glucose may also appear due to the presence in the saliva of a small quantity of mal-

tose. The following scheme illustrates these changes:

Ptyalin has no action upon cellulose and for this reason the starch must always be cooked in order that the cellulose envelope surrounding the starch grains may be broken. Boiling also causes hydration of the starch molecule itself, and renders it more easily disrupted by the amylase.

(2) **PREPARATION OF THE FOOD FOR SWALLOWING BY ALTERING ITS CONSISTENCY.** This is one of the most important functions of the saliva: the food is moistened, thus enabling it to be rolled into a plastic mass, and given a lubricant coating. Claude Bernard showed that a horse with parotid fistula had the utmost difficulty in swallowing dry hay or oats.

(3) **SOLVENT ACTION.** Taste is a chemical sense. All solid substances, in consequence, in order that they may stimulate the taste buds must be dissolved in the saliva.

(4) **CLEANSING ACTION.** The constant flow of saliva exerts a very necessary cleansing effect. The mouth and teeth are rinsed and kept comparatively free from food residues, shed epithelial cells, foreign particles, etc.; in this way the saliva inhibits the growth of bacteria by removing material which may serve as culture media. One has but to consider the foul condition of the mouth in certain fevers when the salivary secretion is suppressed, in order to realize how important its function is in this regard. Then, decomposing organic material swarming with bacteria (*sordes*) collects upon the teeth and lips, and must be removed by artificial means.

(5) **MOISTENING AND LUBRICATING ACTION.** The saliva by moistening and lubricating the soft parts of the mouth and lips keeps them pliable and resilient for the purposes of articulation. Frequent sips of water are almost essential for some public speakers, in whom as a result of evaporation from the mouth during speech, the supply of saliva is insufficient.

(6) **EXCRETORY.** Many substances both organic

and inorganic are excreted in the saliva. Drugs such as mercury, potassium iodide, lead, etc., when introduced into the body are excreted in part by the saliva. Severe inflammation of the oral mucosa (stomatitis) may be caused by the excretion of excessive amounts of mercury by this route. The blue line on the gum margins in lead poisoning is due to the metal having been excreted in the saliva, and deposited as the sulphide. The sulphur is provided by organic material contained in the tartar formed on the bases of the teeth. For this reason the discoloration of the gum does not occur where teeth are absent. In chronic nephritis the saliva contains a high percentage of urea; and sugar sometimes appears in severe diabetes; in parathyroid overdosage the calcium concentration of the saliva is elevated. Several types of microorganisms, some intensely virulent, e.g., the virus of hydrophobia and anterior poliomyelitis are excreted in the saliva. The latter disease has been reproduced in monkeys by injecting the saliva of an infected person.

In this connection it may be added that mumps, which is usually looked upon as a specific inflammation of the parotid gland, is more likely a general disease, since other organs, e.g. ovary, testicle, cerebral meninges, etc. unconnected in any way with the salivary glands are often seriously affected. The parotid inflammation is probably incidental and results from the passage of the infectious agent through the gland into the saliva.

(7) THE RÔLE PLAYED BY THE SALIVARY GLANDS IN THE REGULATION OF THE WATER BALANCE OF THE BODY. When the water content of the body is adequate the saliva is secreted continuously into the cavity of the mouth either by the main glands or by the innumerable small mucous glands that are scattered over the surface of the buccal mucosa. When, however, large quantities of fluid are lost from the body either through the sweat, bowels, kidneys, evaporation from the lungs or from the loss of blood, the salivary glands, in common with the other tissues, are subjected to the dehydrating effect; salivary secretion is suppressed. Drying of the oral mucous membranes, and the consequent stimulation of afferent nerves of the mouth and

pharynx arouses the sensation of thirst (p. 521). This sensation may be looked upon as an essential part of a protective mechanism against the depletion of body fluid. It serves to warn the individual that the body's water supplies require to be replenished.

The actions of drugs and chemicals upon salivary secretion

Serous secretion is stimulated by adrenaline, and ephedrine; acetylcholine, muscarine, pilocarpine, physostigmine (eserine), and histamine increase the mucus secretion. Atropine which antagonizes acetylcholine, and ergotamine which paralyzes sympathetic effects, inhibit secretion. Quinine paralyzes the effects of both nerves.

Disturbances of salivary secretion

Permanent suppression of the salivary secretion—*xerostomia* or *ptyalism* as it is termed—is an unusual condition; little is known regarding the mode of its production. Temporary suppression of salivary secretion is more common and occurs in emotional states and in fevers, or as already mentioned, when the water content of the tissues is lowered. Excessive salivation or *ptyalism* is not unusual and is often particularly troublesome in pregnancy, its cause in the later state is unknown; it is possibly of reflex origin, or due to some metabolic product acting in a drug-like manner upon the gland cells or the secretory nerves.

As a result of irritation of the gastric mucosa, in duodenal ulcer, or in lesions of the esophagus, such as carcinoma or spasm of the cardiac sphincter, salivation occurs as a reflex phenomenon, and may be pronounced (esophago-salivary reflex). The latter reflex is usually readily elicited in a normal person by the passage of a stomach tube or an esophageal sound. Since the glands respond to mechanical stimuli, painful or otherwise, the salivation associated with abnormal conditions in the mouth, e.g., a carious tooth, carcinoma of the tongue, etc. is not surprising.

When the reflex secretion is the result of stimuli arising in the stomach, esophagus or duodenum, and is excessive, the saliva may, without the individual's knowledge, pass down the esophagus and collect above the cardiac sphincter. The secretion occurs as a rule shortly after a meal and a short time later a large quantity of fluid may have accumulated, it may then be brought into the mouth in one or two gushes without any vomiting effort or even nausea. The condition is spoken of as *water-brash*.

CHAPTER XXXIX

GASTRIC DIGESTION

STRUCTURE OF THE GASTRIC GLANDS

The secretory cells of the stomach are arranged to form innumerable small individual tubular units, which constitute the gastric glands. These are scattered diffusely throughout the mucosa. Each opens by a single mouth into the bottom of a tiny pit—the *gastric foveola*. In some cases a single foveola receives the secretion of two or more glands. The gastric foveolae dot the mucosal surface in immense numbers; they are lined by columnar epithelium. The latter is of similar character in all parts of the stomach, and is continuous, on the one hand, with the general epithelial covering of the gastric mucosa, and, on the other, with the cells lining the *gland tubules*. In the latter situation the characters of the cells undergo a change, both morphological and functional, and acquire secretory powers of a special nature.

Each gland may appear as a single tubular structure which lies more or less perpendicular to the surface of the mucosa. More usually, its deeper portion is branched or shows an ill-marked bifurcation. The cellular elements of the glands of the fundus and of the greater part of the body of the stomach differ both in minute structure and in the nature of their secretions from those of the pyloric region as well as from those of the mucosa in the immediate neighborhood of the cardia.

(1) The glands of the fundus and body of the stomach

The gland tubule is divisible into a narrow and short superficial part—the *neck*, and a much thicker and longer portion—the *body*, which reaches nearly to the muscularis mucosae. Its blind extremity is club-shaped, indented or branched. The total number of the gastric glands has been estimated at 35,000,000. The cells which constitute the walls of the tubules are of three types: (a) *chief cells of the neck or mucous neck cells*, (b) *chief cells of the body or zymogenic cells*, and (c) *parietal or border cells*.

The *chief cells of the neck or mucous neck cells* together with the chief cells of the body form a continuous lining for the tubule, and upon a superficial examination resemble one another very closely. They are, however, quite different both in minute structure and function. Their morphological differences can be readily brought out by special staining methods. The chief cells of the neck contain granules of mucinogen but no zymogen

material. Their secretion is, in consequence, entirely mucuous in character. These cells are identical with those lining the entire length of the pyloric glands (see fig. 184).

The *chief cells of the body or zymogenic cells*, on the other hand, contain zymogen but no mucinogen

FIG. 184. Fundic glands of the human stomach. Zymogenic cells light; parietal cells dark. (From Maximow and Bloom, after Braus.)

granules. The former are composed of a material which is the precursor of *pepsin*. After grandular excitation the granules become markedly reduced in number; they accumulate again after a period of rest in the same way as has already been described for the zymogen granules of the salivary cells.

The *parietal or border cells* extend throughout the

entire length of the tubule, but are more numerous in the region of the neck. They do not, however, form a continuous layer, but are scattered here and there along the tubule and lie, not against the lumen, but between the chief cells and the basement membrane. They bulge the membrane outwards and in this way give an uneven, nodular or wavy contour to the gland. These cells can be distinguished from their neighbors not only by their location but by their staining reactions. They furnish the hydrochloric acid and the water of the gastric juice, and on this account, are also known as *oxyntic* or *acid secreting cells*. Though separated from the gland lumen by the chief cells they communicate with the former by means of delicate canaliculi which pass between the chief cells. These canaliculi are extensions of a canal system consisting of an exquisitely fine meshwork *within* the body of the parietal cell. Coarse transparent granules are seen in the protoplasm of the parietal cells during rest; depletion of this granular material occurs during activity.

(2) The pyloric, esophageal and cardiac glands

The pyloric glands are shorter but run a more tortuous course. Parietal cells are absent, and the tubules are lined entirely by cells of the same type as the mucous neck cells of the fundic glands. The pyloric glands, in consequence, are capable of forming mucus but not of supplying pepsin or hydrochloric acid to the gastric juice. Their secretion is alkaline in reaction. The glands in the immediate neighborhood of the cardiac orifice—cardiac glands—are also of the purely mucous type and secrete an alkaline juice. Glands almost identical in character are present in the esophagus—at the level of the cricoid cartilage and at its lower end just above the cardia.

THE GASTRIC JUICE; COMPOSITION; ORIGINS AND DIGESTIVE ACTIONS OF ITS CONSTITUENTS

(SEE ALSO INTRINSIC FACTOR, P. 64)

COMPOSITION

The gastric juice is a mixture of the secretory products—pepsin, mucin, and a watery solution of acid—of the three types of cells composing the gastric glands; it also contains a variable quantity of mucous secreted by the surface epithelium.

The main digestive action of the gastric juice is exerted upon protein, which is split into smaller groups of amino acids by *pepsin* and *hydrochloric acid*. It also contains *rennin* which curdles milk and a very weak lipolytic ferment—*gastric lipase*. The composition of fasting human gastric juice as obtained through a fistula is given in the following table (modified from Carlson).

Acidity	Free HCl, 0.40 to 0.50 per cent
	Total acidity, 0.45 to 0.60 per cent
	pH, 0.9 to 1.5

Solids	Organic, including mucin and the various ferments, 0.42 to 0.46 per cent
	Inorganic, 0.13 to 0.14 per cent
Specific gravity, 1.006 to 1.009	
Total nitrogen, 0.051 to 0.075 per cent	

HYDROCHLORIC ACID IN THE GASTRIC JUICE

Prout in the early part of the last century (1824) first demonstrated the presence of hydrochloric acid in gastric juice. The only other instances of a strong acid being formed by living processes is the production of sulphuric acid, probably for defence purposes, by certain molluscs, and the presence of a fluid with a pH as low as 1.0 in the vacuoles of some unicellular organisms. It has been already mentioned that the parietal cells of the fundic glands are responsible for the production of the acid and water of the gastric juice.

The secretion of the parietal cells cannot be collected separately from the other constituents of the gastric juice and, therefore, cannot be subjected to direct analysis. Its composition can be arrived at only by inference. Hollander analyzed canine gastric juice collected from a stomach pouch and has inferred the composition of pure parietal secretion from the fact that, with increasing acidity, the other constituents decline. The acidity when plotted against the neutral chloride gives a straight line expressing an inverse relationship between them. When extrapolated this line comes to a point representing a zero value for neutral chloride and an acidity of 170 m. eq. per liter. From this it is concluded that pure parietal secretion is an isotonic fluid containing approximately 170 m. eq. HCl per liter and free from neutral chloride. Pavlov had come to the conclusion that the acidity of the gastric juice as it left the glands remained constant (regardless of the rate or volume of secretion) at a concentration of about 0.5 per cent. Pavlov's belief in the constancy of the acid concentration as secreted by the glands is supported in the main by Hollander's experimental results and this view is now widely held.

Gray has calculated the energy required for acid production and arrives at a figure of 1.5 calories for a liter of parietal fluid. Accepting the carbonic anhydrase theory of acid formation, he concludes that this amount of energy is probably furnished by the oxidation of about 5 grams of glucose.

The contents of the human stomach after the usual test meal have a total acidity of from 5 to

40 clinical units (p. 439) or from 0.02 to 0.15 per cent of total acid. The gastric juice secreted into the empty stomach after the more powerful stimulus of histamine injection or in response to psychic stimulation has a total acidity of from 80 to 140 clinical units and a pH of from 1.0 to 1.2. At the height of digestion of a mixed meal containing meat, the acidity of the gastric contents may approach that of juice secreted under the influence of histamine. The low acidity of the human gastric contents after a test meal is due to the latter's relatively mild stimulating effect upon the glands as well as to the dilution and neutralization of the juice by saliva, mucus and other constituents of the meal itself. The analyses of histamine juice, as noted above, and of pure juice collected from a fistula indicate, however, that human gastric juice as it is secreted by the glands has probably an acidity equal to that of canine juice.

There is a relationship (in dogs and human subjects) between the acid concentration in the gastric juice and the erythrocyte count (Apperly and Cary). In severe anemia due to hemorrhage free acid disappears from the gastric juice; as blood regeneration occurs it reappears, its concentration increasing to a maximum when the red cell count reaches the normal value. If the erythrocyte count rises above the normal level (e.g., in polycythemia) the acid concentration steadily falls again to low values.

The origin of the hydrochloric acid

Claude Bernard was one of the first to investigate the question of the origin of the acid. He injected potassium ferrocyanide and lactate of iron into an animal's veins. These substances give the Prussian blue reaction in the presence of free mineral acid. The mucosa of the stomach was turned blue after the injection, but no discoloration was observed in the gland cells or in the lumina of the glands. He concluded, therefore, that the glands secreted some unknown product, which, upon reaching the surface of the mucosa, gave rise to the acid.

Similar experiments were carried out by Fitzgerald, and later, vital dyes which changed color at definite pH values were employed by Harvey and Bensley. The results of these two groups of investigators were not in agreement, the former claiming that the acid was formed within the fine intracellular canaliculi, the latter that it was formed within the lumen of the tubule. Harvey and Bensley suggested that NH_4Cl was secreted into the tubules and through selective re-absorp-

tion of ammonia, HCl was formed. Subsequently, however, Ivy by mean of a Pavlov pouch and the use of vital dye indicators demonstrated that during secretion the cells have a pH ranging somewhere between 6.8 and 3.0. A more precise value was not determined, but the result indicates that the site of acid formation is definitely intracellular.

The ultimate source of the acid is undoubtedly the sodium chloride of the blood. Kahn showed many years ago that, if an animal be fed for some weeks upon meat, deprived of its chlorides by prolonged boiling in distilled water, acid-free gastric juice was secreted. Also the continued loss of gastric juice from the body results in a marked fall in blood chloride. If bromide is fed to an animal which has been deprived of salt for some time hydrobromic acid appears in the gastric juice.

Several theories of the chemical processes concerned in the formation of hydrochloric acid from the blood chloride have been advanced. Many believed reactions represented by the following equations were responsible

Collip by microchemical methods obtained important evidence in support of this conception. He found that the parietal cells are exceptionally rich in phosphates, but during rest chlorides are absent. When the glands became active however a remarkable increase in the cell chlorides occurred. Nevertheless, it is difficult to detect any difference between the concentrations of chloride in the arterial and venous bloods of the gastric mucosa.

The relationship between the CO_2 content of the blood and the secretion of acid in the gastric juice has been demonstrated by several workers. Hyperventilation (blowing off CO_2) reduces, and breathing CO_2 rich mixture increases, the acid secretion. Apperly and Crabtree found that the gastric acidity in man varied directly with the bicarbonate content of the plasma. Browne and Vineberg have demonstrated that the gastric secretion induced by vagal stimulation in dogs is inhibited when the CO_2 content of the plasma falls below 30 volumes per cent as a result of hyperventilation but is restored again when the CO_2 percentage of the inspired air is raised.

Davenport has reported a high concentration of carbonic anhydrase in the parietal cells of the gastric mucosa, and suggests that acid secretion is

proportional to the rate of formation of H_2CO_3 from CO_2 and H_2O . It is significant that thiocyanate and sulphanilamide inhibit the action of carbonic anhydrase as well as the secretion of acid by the gastric mucosa of dogs. These observations have led to the formulation of the *carbonic anhydrase theory* of acid production by the gastric mucosa. According to this theory, as advanced by Davenport, the acid is formed by a reversed chloride shift. It will be recalled (p. 106) that the blood in passing through tissues, such as muscle, receives CO_2 which diffuses into the red cells and is there hydrated to H_2CO_3 by the action of carbonic anhydrase. The carbonic acid ionizes, the HCO_3 ion diffusing into the surrounding plasma and the Cl ion from the plasma into the cells. Electrical equilibrium is thus maintained. In the gastric mucosa H_2CO_3 is formed from CO_2 by the action of carbonic anhydrase, the bicarbonate ion (HCO_3) then diffuses into the plasma and from the plasma into the red cells leaving the H ion in the gastric mucosa. Chloride ions leave the red cells (reversed chloride shift) and pass then from the plasma into the parietal cells; here they are united with H ions to form HCl .

The relation of gastric secretion to the acid-base-balance

A reduction in the excretion of acid by the kidney—the so-called *alkaline tide of the urine*—occurs after a meal. This was attributed to the loss of HCl in the gastric juice. Higgins, and later, Dodds and Bennett found that a rise of from 2 to 5 mm. in the CO_2 tension of the alveolar air occurred half an hour or so after meals; a corresponding fall below the normal level was reported to follow about one and a half hours later. These changes have been looked upon as compensatory reactions brought about by the loss of acid in the gastric juice, and of alkali in the pancreatic juice, respectively, which served to maintain the normal acid-base balance of the body fluids. Though the reduced excretion of acid by the kidney and the rise in the CO_2 tension of the alveolar air and plasma do actually occur during normal gastric digestion, recent work has seriously questioned the generally accepted explanation that the phenomena are due to the secretion of HCl (see p. 395).

When, on the other hand, abnormally large quantities of gastric juice are lost from the body, as in pyloric obstruction with persistent vomiting, or in intestinal obstruction, a profound effect upon the acid-base balance is produced. A fall in blood chloride leading to a state of compensated or uncompensated alkalosis results; tetany may occur. Dragstedt and Ellis have also shown that, in animals, drainage of the gastric juice to the exterior through a fistula results in a reduction of 50 per cent in the blood chloride, alkalosis,

marked dehydration and a rise in the nonprotein nitrogen of the blood. Severe depression occurred ending in death.

THE ORIGINS AND ACTIONS OF THE GASTRIC ENZYMES

PEPSIN is derived from the chief cells of the fundic glands. The zymogen granules in the cytoplasm of these cells are believed to represent the mother substance of the active ferment. Pepsin is active only in acid media; the optimum pH value for its action is about 1.5 (Sorensen). The optimum pH varies, however, in accordance with the particular protein which is being digested. Thus, the optimum pH for the digestion of casein is 1.8, for the digestion of gelatin 2.2. At a pH of 5.0 the action of pepsin is almost abolished. The digestive action of pepsin is confined to protein which it splits into proteoses and peptones. Northrop has obtained pepsin in crystalline form; it is protein in nature.

The first stage in peptic digestion is the action of the acid upon protein to form *acid metaprotein*. The latter is insoluble in water and neutral solutions but soluble in the acid secretion of the stomach. The acid metaprotein is then acted upon by pepsin. The protein molecule is constructed of many amino-acids (p. 538), the greater proportion of which, it is generally believed, are linked together by their amino (NH_2) and carboxyl (COOH) groups. This is spoken of as the *peptide linkage*. The function of the different proteolytic enzymes of the digestive juices (gastric, pancreatic and intestinal) is to break the protein molecule into smaller and smaller fragments containing successively fewer numbers of amino-acids. A molecule of water is taken up (hydrolysis) as the first step in the process and cleavage occurs at the $\text{CO} - \text{NH}$ junction.¹ In the final stage of protein disintegration the molecule is completely disrupted and its individual "building stones"—the amino-acids—separated from one another. This ultimate stage must be reached before protein material can be made use of by the body. Gastric digestion of protein does not go beyond the peptone stage. The action of pepsin (in vitro) is reversible. Wasteney and Borsook have demonstrated the synthesis of protein by pepsin from a concentrated

¹ Though this type of cleavage is unquestionably effected by the pancreatic and intestinal proteolytic enzymes, some have doubted that pepsin is capable of breaking the peptide linkage and have suggested that it attacks some other type of linkage in the protein molecule (see diketopiperazine linkage, p. 540). The evidence, however, is strongly in favor of the view that the peptide linkages are broken by peptic action.

peptic digest of albumin. The optimum hydrogen ion concentration for the synthetic action is at pH 4.0.

GASTRIC RENNIN (OR RENNIN). This, the milk-curdling ferment, is generally believed to be a product also of the chief cells of the fundic glands. Its concentration is low in the gastric juice of the adult. According to some observers, it is absent from adult human gastric juice, the milk-curdling power of the juice being due to pepsin. Rennin is especially abundant in the gastric mucosa of young animals while pepsin is present in minimal amounts. The optimum pH for the action of rennin is between 6 and 6.5 and it is quite inactive at the pH of the gastric contents of the normal adult. In the infant, however, the pH of the gastric contents (5 to 6.5) is around the optimum for the action of this enzyme.

The clotting of milk by rennin shows a certain resemblance in several of its chemical and physical features to the clotting of blood (p. 88). In each instance a soluble protein is rendered insoluble as the result of the activity of a ferment, and in order that this shall occur it is necessary that calcium salts be present in ionized form. In both processes a clear incoagulable fluid, whey in the case of milk, serum in the case of blood, can be expressed or separates spontaneously when the coagulum is allowed to stand. Oxalates and citrates by precipitating the calcium prevent the clotting of either of these fluids. Gastric rennin when added to milk kept at body temperature causes a change in the soluble *casein* (caseinogen) splitting it into a *proteose-like* substance (*whey protein*) which remains in solution, and *paracasein*. The latter is soluble itself but upon combination with calcium forms an insoluble compound, *calcium paracasein* which is thrown down to form the clot or curd. The protein (paracasein) of the curd subsequently undergoes peptic digestion in the usual manner. The softer and more finely flocculent the character of the curd that is formed, the more readily is it attacked by the proteolytic ferments. According to Pavlov the admixture of mucus with the milk renders the resulting curd softer in consistency.

Gastric lipase is a weak fat-splitting enzyme. It differs in an essential manner from the lipases of the pancreatic and intestinal juices in that it acts in an acid medium, and is reduced in activity and finally destroyed by alkali. Its pH optimum ranges between 4 and 5. At a pH of 2.5 its action ceases. It is assumed that gastric lipase is also secreted by the chief cells of the fundic glands, though proof of this is lacking.

Owing to its very weak action gastric lipase is of little practical importance, in adults at any

rate. It is soon rendered inactive as the acidity of the gastric contents rises during digestion, and any action which it may have, is exerted only upon fats in a state of very fine emulsion, e.g., milk, yolk of egg, etc. On this account it may possibly be of greater importance in infants in whose stomachs it is found at, or shortly after birth, and whose gastric contents have a pH more favorable for its action. The whey of mother's milk is said to enhance the action of gastric lipase in infants. Nevertheless, it is questionable whether this enzyme even in infants possesses any real digestive value.

According to some observers digestion of fat in the stomach may be accomplished by pancreatic lipase that has regurgitated through the pylorus. But since pancreatic lipase acts best in a decidedly alkaline medium its optimum pH being 8, and very weakly in an acid medium, its action must be slight so long as the gastric juice possesses its normal acidity. If, however, this is depressed or absent the gastric digestion of fat may be effected to a considerable extent by this means. It is to be remembered in this connection that a meal of fat depresses gastric acidity. Fat also increases duodenal regurgitation which by aiding neutralization may bring about the reaction suitable for the activity of pancreatic lipase.

Gastric mucin

Mucin is a glycoprotein (p. 539). It is secreted by the cells of the pyloric and cardiac glands and by the mucous neck cells of the fundic glands. It is therefore a constituent of pure gastric juice (dissolved mucin). It is also a constituent of the mucous secretion of the ordinary epithelial cells (goblet cells) of the gastric mucosa (surface epithelium mucus). Ivy found that the juice collected from pouches fashioned from the pyloric part of the stomach of dogs was mucoid, viscous, tenacious and transparent with a pH of 7.0 to 7.5.

Gastric mucin has a high acid combining power. It coats the interior of the stomach, and by reducing the free hydrochloric acid serves to protect the mucosa from the action of the gastric juice. Quite apart from its power to lower the acidity of the gastric juice Babkin and Komarov find that mucin inhibits peptic activity. This anti-peptic action of mucin is due to its constituent, mucoitin-sulphuric acid. The protective properties of gastric mucin have been put to practical use by Fogelson and by Ivy and Kim, in the treatment of gastric and duodenal ulcer. The mucin is prepared from hog's stomach. One gram of such a preparation combines with

15 cc. of a 0.5 per cent hydrochloric acid and Fogelson found that about 60 grams was more than sufficient to neutralize the acid secreted in response to the injection of 1 mg. of histamine. Also when $\frac{1}{2}$ ounce of mucin together with 1 pound of meat was given to a dog, free acid did not appear in the stomach until the lapse of from 5 to 7 hours.

THE CHYME

The changes in the food brought about by the various chemical and physical processes that have been described as constituting gastric digestion may be briefly summarized. Much of the *protein* of the food is reduced to simpler materials which are soluble in the fluids of the stomach. The *fats* undergo some degree of emulsification. Other materials, such as the *sugars* taken preformed with the food or those derived from the partial digestion of the *starches*, pass readily into solution. The remainder of the *starch* is in part rendered soluble (soluble starch and dextrins) by salivary action and in part reduced to a fine state of mechanical division. The gastric movements (p. 484) cause these various elements, which differ widely in their chemical and physical natures, to become thoroughly mixed with one another and with the gastric juice until finally the food assumes a semi-fluid, more or less homogeneous, creamy or gruel-like consistency. This material, now known as the *chyme* (Gk. *chumos*—juice) is definitely acid in reaction; it passes through the pyloric opening, not all at once but from time to time as it is formed. The food having reached this stage is suitably prepared for further digestion by the intestinal juices.

THE RELATIVE IMPORTANCE OF CHEMICAL AND MECHANICAL FACTORS IN GASTRIC DIGESTION

Borelli and the mechanical school of physiologists of the seventeenth century saw digestion simply as a process in which crushing, grinding and mixing of the food, and the expression of its nutritive juices were the prime features. Chemical processes were scarcely considered. The second stomach or gizzard of the bird in which resistant objects, even glass beads, are crushed was pointed to in support of these mechanical conceptions of gastric digestion. Not until the experiments of Réaumur (1683–1757) and Spallanzani (1729–1799) was the chemical character of gastric digestion appreciated. They showed

by a crucial experiment—the digestion of meat by gastric juice in a test-tube—that gastric digestion was a chemical process, and not simply a mechanical disintegration of the food. Ever since, more stress, perhaps, has been laid upon the chemical than upon the mechanical side of digestion. It is probable, however, that the latter is in reality of just as great or even of greater importance than the chemical factor. Subjects in whom the gastric juice is entirely absent usually suffer no apparent difficulty in the digestion of food and there may be no gastric symptoms whatsoever. The larger part of the stomach may be removed and, provided that the consistency of the food is made suitable, little digestive inconvenience results. After complete removal of the human stomach, protein and fat digestion have been found to be perfectly normal, but there may be depression of intestinal motility as a result of the unavoidable severance of the vagus nerves. Purely mechanical factors, on the contrary, very frequently give rise to digestive disturbances, and it is probably true that the *immediate* factors responsible for the production of the various symptoms of gastric disease are always mechanical in nature. Disturbances of gastric motility, for example, may cause discomfort, pain and other dyspeptic symptoms. The stomach contents may be retarded in their passage into the duodenum as a result of spasm of the pylorus or of an organic blockage. On the other hand, a too rapid evacuation of the stomach may, by permitting food to enter the duodenum in an improperly prepared state, induce ill effects. The chemical processes of gastric digestion, therefore, important as they are, must not be allowed to overshadow in our minds the mechanical factors. A prime function of the stomach is to break up the food, to add fluid to it and reduce the entire mass to a semi-fluid consistency, in which state it can be more readily acted upon by the digestive enzymes of the intestine. The movements of the stomach will be discussed in Chapter XLIII.

THE ANTISEPTIC ACTION OF GASTRIC JUICE. By virtue of its high acidity normal gastric juice has an important bactericidal action. Streptococci, staphylococci and *B. coli* are destroyed, the contents of the duodenum in health being virtually sterile. In permanent or temporary achlorhydria, on the contrary, the duodenum is very quickly invaded with microorganisms from the colon. Following perforation of a gastric or duodenal ulcer, for example, the gastric secretions are suppressed as a result of the shock occasioned by the accident, and peritonitis supervenes.

after sufficient time has elapsed for the duodenal fluids to become infected in this way. The importance of early operation is self evident.

The Effects of Gastrectomy upon Certain Non-digestive Functions. Since the stomach plays an important part in erythropoiesis (p. 64), it might be expected that anemia of the pernicious type would follow its removal but, as a matter of fact, pernicious anemia is rarely seen after total gastrectomy either in man or in animals. The microcytic hypochromic type, on the other hand, is not uncommonly a result and is most probably due to defective absorption of iron caused by the lack of hydrochloric acid (p. 60). It responds to iron administration. Ivy and his associates have reported rarefaction of the bones in puppies leading to gross deformities of the limbs following gastrectomy. Removal of the stomach in growing monkeys caused

arrested growth and a condition of the bones resembling osteitis fibrosa cystica (p. 708), together with hypocalcemia and enlargement of the parathyroid glands. The condition is the result apparently of impaired calcium absorption due in turn to the absence of hydrochloric acid (p. 711); of it can be prevented to a large extent or partially corrected by adding soluble calcium salts to the diet. As well as the one just mentioned, Ivy lists three other causes of the osteoporosis; (a) the absence of the reservoir function of the stomach, imperfectly digested food being passed rapidly through the upper part of the intestine from where the greater part of the calcium is normally absorbed; (b) the postprandial acidosis resulting from the secretion of alkaline intestinal juices in the absence of the acid gastric secretion and (c) encroachment of the red marrow (due to the anemia) upon the osseous tissue.

CHAPTER XL

GASTRIC DIGESTION (*Continued*)

THE SECRETION OF GASTRIC JUICE

THE INNERVATION OF THE GASTRIC GLANDS

Stimulation of the vagus nerve causes the secretion of juice high in peptic power and strongly acid. According to Alley and Babkin the glands of the lesser curvature respond more readily to vagal stimulation than do those of the greater curvature, and secrete a stronger juice. This fact may be of significance in the development of gastric ulcer (p. 443). Baxter has shown that stimulation of the sympathetic causes the secretion, mainly from the pyloric glands, of an alkaline mucoid juice which is very low in peptic power; this secretion is unaffected by atropine but is annulled by ergotamine (which paralyzes motor and secretory sympathetic fibers). Vineberg's results indicate that the vagus controls the secretion of mucus by the mucous neck cells and the surface epithelium of the gastric mucosa. The influence exerted by the sympathetic upon the peptic and oxyntic cells is not definitely known. According to some observers its effect upon these elements is inhibitory.

THE QUESTION OF THE CONTINUOUS OR INTER-DIGESTIVE SECRETION OF GASTRIC JUICE

Pavlov found that the secretion of gastric juice in dogs was intermittent; beyond the secretion of some alkaline mucus the gastric glands in the absence of food or psychic influences (see below) remained at rest. This conclusion has been confirmed by the recent experiments of Babkin. But in man, juice is secreted continuously in fairly large amounts; but this fact does not necessarily indicate a fundamental difference between the activities of the glands of the human and canine stomachs. The shorter intervals between meals, and psychic influences which are impossible to eliminate in the case of the human subject, are probably responsible for the continuous and apparently spontaneous secretion. The secretion is increased during sleep.

THE PHASES OF GASTRIC SECRETION

It has been known for many years that it is not a necessary condition for the excitation of the gastric glands that food shall enter the stomach.

The mere presence of food in the mouth calls forth an abundant secretion of gastric juice. The flow of juice that occurs in this instance is due to a nervous reflex and is termed the *psychic or cephalic phase of gastric secretion*. It is also well known that the glands are stimulated by the presence of food in the stomach, even after all nerves connecting the organ with the central nervous system have been severed. This secretion of gastric juice which results from influences arising within the stomach itself is referred to as the *gastric phase*. Secretion of juice also results from influences arising from the intestine after the food has passed through the pylorus. This is the *intestinal phase of gastric secretion*.

THE PSYCHIC OR CEPHALIC PHASE

The psychic secretion of gastric juice was originally demonstrated by Pavlov, in dogs. To study in detail this phase of gastric secretion and other problems in gastric physiology he devised the following operation. A longitudinal incision was made in the body of the stomach in the region of the greater curvature (fig. 185AB). This included both anterior and posterior walls of the organ, and starting near the pyloric region ended about the middle of the fundus. The concave flap formed in this way, and which remained attached to the fundic region by its base, was then turned down and its cut edges, as well as those of the main stomach, sutured together. Thus was fashioned a small tube lined by normal gastric mucosa with an open free end (fig. 185S). Complete isolation of the cavity of the tubular pouch from the main cavity of the stomach was accomplished by reflecting a flap of mucosa from the gastric walls at the junction of the pouch with the fundus and fixing it in position to form a partition between the two cavities. The free, open end of the pouch, or *miniature stomach*, as it is usually called, was then sutured into the abdominal wound. Through the fistula established in this way pure gastric juice uncontaminated by food could be collected while digestion was proceeding normally in the remainder of the stomach. The main stomach was also fastened to the abdominal wall and a fistulous communication established between it and the exterior. The advantage of

this operation over previous ones contrived for a similar purpose (e.g., the Heidenhain pouch) is that, on account of the longitudinal direction of the incision, a minimum amount of damage is inflicted upon the nerve supply of the pouch.¹ Furthermore, a comparatively large pouch—about one-tenth the size of the whole stomach—is procured by this means. The miniature stomach is assumed to portray faithfully the behavior of the main stomach under various experimental conditions. This assumption has been justified by control

FIG. 185. The Pavlov pouch. Upper drawing shows line of incision to form a flap. C, cardiac part of stomach. Lower drawing shows the completed operation. S, pouch; the mucous membrane has been reflected to form a partition between the main cavity of the stomach and the miniature stomach. A, A, abdominal wall (after Pavlov).

experiments in which the secretion of the miniature and of the main stomach were compared.

Sham feeding

In the study of the psychic phase of gastric secretion it is, of course, essential that no food shall be allowed to enter the stomach. In order to secure this the esophagus was divided in its upper third; the lower end of the upper section was then brought out through the skin wound and fixed in position by sutures (fig. 186). A miniature stomach and a gastric fistula leading into the main

¹ This claim according to Jemerin and Hollander is unwarranted.

portion of the stomach were also produced, in the manner already described, for the purpose of observing the secretory responses, as well as for feeding the animal when necessary. An animal prepared in this way could eat and enjoy its meals but the food after being swallowed simply issued from the esophageal opening in the neck. When "*sham or fictitious feeding*," as this procedure is called, is performed a profuse secretion of gastric juice follows after a brief latent period. In some experiments in which sham feeding was maintained for 5 or 6 hours, as much as 700 cc. of pure gastric juice were secreted into the stomach. A proportionately smaller amount was secreted into the artificial pouch. Even after a single 5-minute

FIG. 186. A two-stage operation for making an esophageal fistula. 1. First stage, showing esophagus exteriorized. 2. Second stage, performed four or five days later, showing excision of elliptical segment of anterior esophageal wall. 3. Completed operation, lateral view. (After Dragstedt and associates.)

period of fictitious feeding the secretion persists for from one to three hours, and produces 200 or 300 cc. of juice. The secretion is rich in pepsin. Division of the vagi completely abolishes the response. It is, therefore, undoubtedly due to a reflex mediated through these nerves. The quantity of juice varies with different foods, but the only quality of the food which appears to influence the psychic secretion is its palatability; the chemical or physical properties of the food are unimportant in this regard. Meat for instance for which the animal has a keen relish produces a juice of the greatest abundance and richest in ferment. Bread or other materials not particu-

larly appetizing cause less secretion, and the juice has less digestive power. A more pronounced reaction occurs if the animal is hungry. In marked contrast to the activity of the salivary glands, no secretion can be evoked by placing inedible substances in the mouth, or those which are injurious or nauseous, such as acid, pepper, asoefetida, etc. Indeed these may cause inhibition of a secretion that is already in progress. All these facts point to the involvement of the higher nervous centers in the reflex mechanism. The pleasure of eating, the agreeable stimulation of the organs of taste and the gratification of appetite are essential conditions.

It is not even necessary that the food should enter the mouth in order to elicit the gastric response. Provided the food is sufficiently appetizing simply sight or smell of it will cause secretion. In other words a *conditioned reflex* can become established for gastric as well as for salivary secretion (p. 420).

The importance of the psychic secretion may be judged from the fact that in its absence gastric digestion is seriously hampered. When, for example, a piece of meat or bread is placed in the stomach through a fistula while an animal is sleeping or, by the diversion of its attention, is unaware of the introduction of the food, much less is digested in a given time than when the animal has been shown the food before introducing it into the stomach or has been given it by "sham feeding."

Babkin has shown that a time element may be prominent in the conditioned response; he found that animals which were accustomed to being fed at a certain hour each day secreted large amounts of gastric juice at this time though no food was offered.

The psychic secretion in man

In man, the cephalic phase causes the secretion of from 50 to 150 cc. within 20 minutes (Ivy). Richet observed long ago that in a subject who had suffered esophageal stricture and into whose stomach an artificial opening (fistula) had been made for feeding purposes, secretion of gastric juice occurred upon the entrance of food into the mouth. Within recent years Carlson has carried out extended observations upon a subject who had had a similar operation performed for closure of the esophagus resulting from the ingestion of a corrosive in childhood. This subject therefore was already prepared, like Pavlov's dogs, for sham feeding, the only difference being that there was no opening in the neck, it being necessary to

spit out the food after chewing it. All the findings of Pavlov were, in the main, confirmed in the case of this subject. The influence of appetite or the desire for the food was particularly well brought out. The subject especially enjoyed the dessert, and the curve of gastric secretion showed the most pronounced rise when sweets or fruit, such as oranges, were chewed. The secretion, however, did not last for as long as in Pavlov's experiments, but commenced to decline as soon as the stimulation of the taste buds had ceased (fig. 187). Nor did the mere sight or smell of food (conditioned stimulus) evoke a response except when in one instance the subject was sent from the laboratory to select his meal from a near-by cafeteria. In this instance there was a very definite response to the sight and smell of the food. Several other observers have reported the existence of definite conditioned reflexes for gastric secretion in man.

FIG. 187. Typical curve of secretion of gastric juice collected at 5-minute intervals during the mastication of palatable food for 20 minutes. The rise in secretion during the last 5 minutes of mastication is due to chewing the dessert (fruit) for which the person had an especial fondness. (After Carlson.)

The psychic effect upon gastric secretion has been demonstrated also by Bennett and Venables upon subjects during hypnosis. A suggestion made to the subject that he was eating some savory morsel of food called forth a secretion of juice. The suggestion of nauseating substances inhibited secretion. Psychic influences of an inhibitory nature have also been demonstrated by Hawk and associates who found that worry and anxiety retarded digestion. A meal disgusting in appearance and foul smelling (indol was scattered over the table) had a similar effect.

The application of these experimental results to dietetics is obvious. Foods agreeably flavored and attractive in appearance, impressions received from a meal prepared in a pleasing way, and, probably also, sensations aroused by the surroundings yet not directly concerned with the food itself, have all an effect upon gastric secretion. The impulse which guides the gourmet is sounder physiologically than that which impels the glutton.

The question of calories and the relative digestibilities of the various foodstuffs should not be allowed to obscure the psychic element entirely in these matters, for the "delights of the table" have true digestive value. These facts are expressed in the words of Pavlov "appetite spells gastric juice" or in the hospitable words of Macbeth "Now good digestion wait on appetite and health on both." Custom seems to have discerned this truth, for it has decreed that the meal shall begin and end with the more strongly flavored and appetizing morsels.

THE GASTRIC PHASE. THE SECRETION OF GASTRIC JUICE UPON THE ENTRANCE OF FOOD INTO THE STOMACH

When food is present in the stomach the secretion of gastric juice continues for a much longer time than can be accounted for by the psychic secretion. The factors concerned in this secretory phase must now be considered. In the first place, "What is the nature of the adequate stimulus? Is it mechanical—the mere contact of the food with the gastric mucosa? Or is it chemical?"

(a) **MECHANICAL STIMULI.** Pavlov demonstrated, apparently quite conclusively at the time, that mechanical stimulation of the gastric mucosa was entirely without effect upon the secretion of gastric juice. A glass rod having its tip covered with blue litmus paper remained unaltered in color when rubbed vigorously over the mucosa of the stomach. It was wetted by alkaline mucus but there was evidently no secretion of acid. Streams of sand when blown with considerable force against the mucosa so as to cause a more diffuse stimulation were also ineffective. More recently, however, Ivy and Farrell have shown that some degree of glandular excitation is caused by mechanical stimulation—particularly by the application of a distending force. There is an unusually long latent period and this is probably the reason that the effect was not discovered previously. The amount of juice secreted is, however, not great and, therefore, this type of stimulus cannot be wholly or even largely responsible for the flow which food induces by its presence within the stomach.

(b) **CHEMICAL STIMULI.** It was noted by Pavlov that certain articles of food such as bread and meat, which could not differ to any significant degree from one another in their physical effects upon the gastric mucosa, produced, nevertheless, greatly different secretory responses. Bread introduced through a fistula into a stomach that had been thoroughly dried of all residual juice,

and with the vagus nerves cut (in order to eliminate the psychic secretion), caused no excitation of the glands. Meat, on the other hand, under the same conditions, evoked an abundant flow of juice. The contrary results in the two instances must have been due it was argued, to chemical differences between the respective foods. The adequate stimulus was evidently chemical in nature and dependent upon substances contained in the meat. The various constituents of meat—its salts, water, protein and extractives—were then each investigated in turn for their secretagogue effect. Each was introduced into the main stomach, while the miniature stomach was observed for any signs of secretion.

With the exception of the *extractives* none of these components of meat had any pronounced effect. The *ash of meat* was without any effect whatever. *Water* caused a slight secretion (Reh-fuss has shown that water causes a much greater excitation in the human stomach than Pavlov reported for dogs). *Protein* itself, as in egg white, when the effect of its contained water was taken into account, appeared to be quite inert. Meat broths, meat juices and commercial extracts, such as Liebig's, all of which are rich in the watery extractives of meat, elicited a copious secretion.

Not only meat extractives but the *products of protein digestion*—*proteoses* and *peptones*—were equally powerful.

Having determined the specific stimulants for the gastric phase of gastric secretion, namely meat extractives and the products of peptic hydrolysis, the next question to be answered is "Through what mechanism do these substances act?" There are several possibilities. They might conceivably act (1) by direct stimulation of the gland cells; (2) through the stimulation of the afferent nerves in the gastric mucosa, thus bringing about secretion through a central reflex; (3) through their absorption into the blood stream, and their carriage therein to the glands; (4) through the local nerve plexus in the gastric wall, or, finally (5) by the liberation of a hormone from some part of the gastric mucosa which would then serve as the ultimate excitant.

The first two of these possibilities are ruled out as primary factors and (3) and (4) are improbable because of the following observations. Excitation of the glands of the miniature stomach occurs when the stimulating substances are placed in the main stomach. Injection of the materials intravenously causes a relatively small secretory response. The secretion occurs after the stomach has been completely isolated from the central

nervous system. The fifth possibility remains to be considered.

A consideration of a hormonal mechanism as responsible for the gastric phase.

The gastrin theory

In 1902 Bayliss and Starling discovered a hormone (secretin, p. 451) in the upper part of the small intestine which had a very powerful effect upon the secretion of pancreatic juice. The discovery of this substance led Edkins a few years later to search for one of a similar nature which might be concerned in the control of gastric secretion. He found that when the pyloric mucosa was ground up and extracted with some of the stimulating substances mentioned above, notably peptones, or with glucose or hydrochloric acid, the extract had a powerful secretory effect when injected intravenously. A simple watery extract was ineffective. Injection of the substances themselves directly into the blood stream was also incapable of causing secretion. Edkins gave the name *gastrin* to the undetermined principle in the active extracts. The conclusion drawn from these results was that gastrin, formed during normal digestion through the action upon the pyloric mucosa of substances derived from the food, was absorbed into the blood stream, and upon reaching the fundic glands excited them to activity.

As a result of later work (Koch, Luckhardt and Keeton) it was found that pyloric extracts were not specific but in common with other tissue extracts contained a secretagogue principle. This observation apparently deprived Edkins' results of any physiological significance in so far as gastric digestion was concerned. Popielski had, in 1920, demonstrated that histamine, which may be isolated from various tissues, was a powerful stimulant to gastric secretion. It was therefore suggested that the active principle in pyloric extracts (*gastrin*) was simply histamine. This view has been amply substantiated. Histamine is a constituent of pyloric extracts; and Sacks, Ivy and collaborators found that if the pyloric tissue were incubated with histaminase (the histamine-inactivating enzyme) before extraction, the preparation had no secretagogue action. This observation has been confirmed by Gavin, McHenry and Wilson who have also shown that in the dog, the tissue of the body of the stomach is richer in histamine than that of the pylorus and that 80 per cent of the total histamine content of the stomach is to be found in the former situation.

Extracts of the fundus (body) have also a great secretagogue action than have pyloric extracts.²

On the other hand, it has been shown definitely by Ivy and Farrell that an excitatory substance of some sort is actually carried in the blood stream during digestion to the glands of the fundus. These observers in a three-stage operation upon a dog, isolated completely a portion of the fundus and transplanted it into the subcutaneous tissue of the abdomen. After the operation, no nervous or direct vascular communications between the two sections of the stomach remained. When the animal was fasting, the transplanted pouch secreted a little mucoid fluid containing a small amount of combined acid, but no free acid. After the animal had been fed and digestion had proceeded in the main stomach for from 2 to 5 hours, an increase in the volume and in the combined acid of the juice secreted by the transplanted pouch occurred; in some instances free acid appeared.

The results of later experiments by Gregory and Ivy on dogs indicate that the blood-borne substance is a hormone. They created two completely denervated stomach pouches. One pouch consisting of a small part of the fundic region was transplanted (transplanted pouch) to the subcutaneous tissue of the mammary gland. The rest of the stomach (main pouch) was separated from the esophagus and duodenum which were then anastomosed. Perfusion of the main stomach with liver extract, which is a potent source of secretagogues, caused the secretion of free acid from both pouches. Mechanical stimulation (distension) of one pouch caused secretion from that pouch but not from the other. It is evident that, since the main pouch and the transplant are connected only through the general circulation, the action of the secretagogues is followed by the passage into the blood of a substance which stimulates the gastric glands, but that mechanical stimulation is incapable of initiating such a mechanism. When the animal was given a meal of bread, meat and milk (which passed directly into the intestine) both pouches secreted free acid in fairly large amounts for several hours.

² The term *secretagogue* may be applied to any substance which excites secretion no matter by what mechanism the secretion is ultimately brought about. The term *hormone* will be used to indicate a secretory extract which is absorbed from the cavity of the stomach or intestine and carried in the blood stream to the gastric glands. The use of the word *hormone* will be confined here to any secretory substance secreted in the gastric or intestinal tissue and conveyed to the glands in the blood stream.

These results still left unsettled the question of the nature—humoral or hormonal—of the food-borne substance, that is, whether the secretagogues themselves were absorbed into the blood stream or whether they acted upon the gastric mucosa to produce a new stimulating substance or to cause a preformed substance to be liberated into the circulation. Anesthetizing the mucosa of the main pouch with procaine prevented the action of the secretagogues in the main stomach as well as in the transplanted pouch. Yet after anesthetization of the transplanted but not of the main pouch, secretagogues exerted their usual effect when introduced into the latter. This proves that the anesthetic does not paralyze the gland cells. Nor does procaine prevent the action of the blood-borne substance formed during normal digestion, once it has entered the blood stream, because secretion from the anesthetized main pouch occurs after the animal has been fed and food has entered the intestine. These experiments pointed definitely to a hormonal mechanism, although the possibility remained that the secretagogues themselves are humoral agents, the absorption of which had been depressed by the anesthetic. In experiments with other secretagogues such as histamine and ethyl alcohol, no evidence of such an effect of the anesthetic was secured.

The pyloric region has been thought by several to be essential for the production of the gastric hormone, but, in other experiments of Gregory and Ivy, pouches from which the pylorus had been removed gave essentially the same response when secretagogues were introduced into the remaining part of the stomach. The pyloric region, therefore, appears to have no special function in this regard.

THE NATURE OF THE GASTRIC HORMONE. The question now arises whether or not the gastric hormone, i.e., the substance liberated into the blood stream when food enters the stomach, is identical with the active principle in pyloric extracts (gastrin). In other words, is histamine the gastric hormone? This question cannot at present be answered definitely. That the activity of pyloric extracts is destroyed by histaminase does not settle the point, for (a) this enzyme has not been proved to be absolutely specific for histamine and (b) it may possibly be that a gastric hormone, not identical with histamine, exists but has not been obtained by extraction. The fact that anesthetizing the mucosa prevents the effect which follows the placing of food in the stomach does not the effect resulting from the injection of

gastrin would seem to indicate that the two substances are not identical. It is conceivable, however, that these drugs merely interfere with the formation of the hormone (whether it be histamine or some other substance) and yet have no effect upon the absorption or action of any hormone which had already been formed in the mucosa. The observation that the juice resulting from histamine injections differs from normal gastric juice suggests, again, that the gastric hormone is not simply histamine. According to Babkin and his associates the gastric juice formed by the stomach of the dog as a result of the injection of histamine or of purified gastrin, though possessing a high acidity, has a low concentration of pepsin. Babkin also points out that though histamine is very readily extracted by acids, hydrochloric acid placed in contact with the pyloric mucosa does not stimulate gastric secretion; a 0.5 per cent solution is actually inhibitory (Alley). Moreover, histological examination of the gland after histamine injections shows an effect confined to the acid-producing cells; in contrast to the appearance after vagal stimulation, the peptic cells were entirely unaffected (Bowie and Vineberg). It is stated, on the other hand, that pepsin is present in fairly high concentration in human gastric juice produced by histamine injections (Bloomfield and Pollard); but in observations upon the human subject the possibility of the enzyme secreted prior to the injection having been simply washed out of the tubules by the secretion of the parietal (acid) cells is difficult to exclude. Indeed, evidence that the high concentration of pepsin was due to washing out of preformed ferment has been obtained by Teby who found that when histamine was administered repeatedly to patients the peptic activity of the juice declined progressively with each successive injection. Bucher and his associates, on the contrary, observed that in animals the pepsin concentration actually increased when repeated small doses of histamine were administered.

The foregoing is a summary of the main experimental facts which argue against histamine being a gastric hormone. The question, however, is very complex and cannot be answered definitely in the face of such conflicting results. But a fresh light has been thrown upon it by the observations of Grossman, Woolley and Ivy who have pointed out that the gastric hormone, which has been demonstrated experimentally and which acts presumably during normal gastric digestion, causes the secretion of a juice low in peptic power. It is also recalled that a hormonal mechanism

for the secretion of pepsin such as may follow vagal stimulation or pilocarpine administration has never been shown to exist. These investigators found that liver extract, which has a powerful secretagogue effect, causes the production of a juice closely similar to that due to histamine, namely, of low peptic power. They conclude that the gastric hormone which has been demonstrated to cause this type of secretion *may be* histamine and that the high concentration of pepsin in the gastric juice secreted under normal circumstances is brought about by some other mechanism.

We can, at least, safely say this much with regard to histamine, or indeed of any known gastric hormone, that in eliciting a secretion of pepsin it is much inferior to nerve stimulation.

It has been suggested that histamine may play a rôle in gastric secretion somewhat different from that just discussed, namely, by serving as a chemical mediator of the vagal control of the parietal cells, i.e., as a "local hormone" liberated by the vagal nerve endings. The facts that histamine is present in the gastric juice, that its concentration in the juice is increased by vagal stimulation and that its content in the body of the stomach is much higher than that of the pyloric region accords with this possibility.

THE INTESTINAL PHASE OF GASTRIC SECRETION

The products of gastric digestion upon entering the duodenum act as chemical excitants to gastric secretion. If a meal of bread and milk is fed to an animal, as prepared in Gregory and Ivy's experiments, a secretion from both the main stomach pouch and the transplant commences within about 2 hours and continues for from 3 to 9 hours. It appears that the mechanism is hormonal in nature and similar to that which stimulates secretion during the gastric phase of digestion, split digestive products acting as secretagogues. Mechanical stimulation of the intestine, as by distension, is ineffective, and, as mentioned on page 435, the application of procaine to the gastric mucosa does not abolish the response. Various substances placed directly in the duodenum, e.g. water, meat extracts, albumoses and peptones, magnesium sulphate, saponin, soaps, etc., have been shown to excite the glands of an isolated stomach pouch. Crider and Thomas found that when the duodenal contents were drained away through a fistula, the response of the gastric glands to a meal was only a third of the normal value. Gastric secretion is inhibited by fat or by acid in the duodenum.

THE INHIBITORY EFFECT OF FAT UPON THE GASTRIC GLANDS

Fat, after it reaches the intestine, inhibits gastric secretion. Later, secretion is stimulated; the mechanism of this secondary stimulation is not clear; it is not due, apparently to soaps. The inhibitory effect of fat is sufficiently powerful to antagonize the psychic phase of gastric secretion and the stimulant action of histamine.

The motility of the stomach is also depressed (p. 485) by fat; hunger contractions are inhibited. The manner in which fat exerts its inhibitory effect upon secretion has been clarified by the experiments of Ivy and of Lim and their associates. A hormone (chalone, p. 670) is responsible. Lim found that fat placed in a denervated isolated pouch was followed by inhibition of secretion in the main stomach. The inhibitory influence, he concluded, was not due to the absorbed fat itself since the effect was not abolished by draining the chyle to the exterior and so preventing absorbed

TABLE 32*

* Modified from Carlson.

fat from entering the general circulation. Fat reduces the quantity and acidity of the juice but depresses especially the peptic power. Ivy and his associates have extracted a substance from the intestinal mucosa which, when injected, produces the characteristic inhibitory effect upon gastric secretion and motility. This material which has been named *enterogastrone* is free from depressor (vasodilator) activity and does not contain secretin (p. 451) nor cholecystokinin (p. 475).

It is capable in maximal doses of causing complete suppression of secretion for from 1 to 5 hours and of gastric motility for 30 minutes. In smaller dosage, it reduces acid and peptic secretion. The effect upon pepsin secretion is not observed after vagal denervation. There is some evidence that the effect upon gastric motility is due to a principle closely associated with but distinct from that which inhibits secretion.

A substance known as *urogastrone* and having effects similar to enterogastrone upon gastric secretion and motility has been extracted from

normal urine by Gray and his associates. Urogastrone was thought at first to be most probably excreted enterogastrone but certain differences have since been demonstrated which indicate that they are separate and distinct substances. Pepsin inactivates enterogastrone but has no effect upon urogastrone.

THE ADAPTATION OF THE QUANTITY AND QUALITY OF THE GASTRIC SECRETION TO THE TYPE OF FOOD. It has been shown by Pavlov and Khizhin that the juices secreted for the three foodstuffs, bread, meat and milk, respectively, differ characteristically from one another, both in quantity and digestive power. Indeed the juice secreted for each type of food is, according to Pavlov so specific and suited to the digestion of the particular foodstuff which calls it forth, that it is possible to predict the character of the juice which will be secreted when a given type of food is fed. He therefore speaks of "meat," "bread" and "milk" juice, respectively. The juice secreted for *meat*, for instance, was found to be greatest in quantity, but intermediate in digestive power between those formed for bread and for milk. *Bread juice* possessed the highest peptic power (about double that of meat juice) but was intermediate in amount. It was suggested that the high ferment value was an adaptation furthering the digestion of the more resistant vegetable proteins. *Milk juice* was both scanty in amount, and poor in peptic power during the first four hours of secretion. The low values of the juice secreted for milk was ascribed to the inhibitory effect of the milk fat. The acidity is highest in meat and lowest in bread juice. In the case of the human stomach meats are recognized to be, as compared with other foods, the most powerful stimulants of acid production. (See table 32.)

The acidity of the gastric juice as collected from the stomach in many instances shows a tendency to vary with the rate of secretion by the fundic glands; when their rate of secretion is slow the juice will be diluted to a greater extent by mucous fluid than when the rate is rapid. It was Pavlov's view that variations in acidity are due entirely to changes in the rate of total secretion into the stomach and that *the acidity of the juice as secreted by the parietal cells is constant* (p. 424). The reverse relation holds between rate of secretion and pepsin concentration, the latter becoming reduced as the secretion rate increases. These relationships are dependent upon the fact that the acid secreted by the parietal cells makes up the bulk of the fluid of the juice. Juice of large volume is therefore highly acid, that of small volume contains a relatively high concentration of pepsin and alkaline mucus. Such relationships hold true, however, only when the same type of secretory stimulus is employed and its intensity varied. When, however, the type of stimulus is altered it appears that the acidity or peptic activity of the juice may vary independently of the rate of secretion. That is, a slow or rapid secretion rate may

be associated with either a low or high acidity, and similarly with the pepsin concentration. Furthermore, the proportions of the three main constituents of the juice, acid, pepsin or mucin, can vary independently of one another. Alley found, for example, that haddock muscle prepared in various ways caused qualitative differences in the juice secreted. Baked haddock increased the quantity of juice and the concentrations of pepsin and mucin. Smoked haddock stimulated the acid production and increased the quantity but the juice was poor in mucin and pepsin. It has been mentioned above that fat exerts a much greater depressing effect upon the peptic power of the juice than upon its acidity or quantity. Histamine provokes the secretion of a highly acid juice containing little or no pepsin, while insulin (p. 438) stimulates chiefly the peptic cells. The different elements of the gastric glands, parietal, peptic or mucous cells, are therefore not necessarily excited to the same extent by a given stimulus; and different types of stimulus affect the respective secreting elements in varying degree.

THE EFFECTS OF VARIOUS CHEMICALS AND DRUGS UPON GASTRIC SECRETION

Alkalis in general have been held to exert a depressing effect upon the secretion of gastric juice. Sodium bicarbonate, for instance, a favorite ingredient of digestive mixtures was investigated by Pavlov in dogs and found to be definitely inhibitory. This observation has been confirmed by Farrell, though others find that the inhibitory effect does not occur unless the dose is excessive, and that in small repeated doses it augments the secretion (Boyd). This seems to be true also of other alkalis, large doses depress but small doses, especially if repeated, may augment the flow of juice, thus alkaline drinks are mildly stimulating. Nor does the inhibitory effect of large doses persist after their discontinuance; on the contrary, hypersecretion not uncommonly follows. The value of alkalis in gastric disorders depends chiefly, however, upon their antacid properties i.e., upon their ability to neutralize the acidity of the gastric contents.

The various preparations of *bitters* are without any appreciable effect upon secretion unless they contain *alcohol*. The latter has a pronounced secretagogue action, causing the secretion of a juice of high acidity and rich in mucin. It is possible that alcohol exerts its secretory action through the liberation of histamine, for it has been shown that the histamine output of the perfused lung of the guinea pig is increased by the addition of alcohol (2-6 per cent) to the perfusion fluid. *Acids* depress gastric secretion which is completely inhibited by the introduction into the stomach

of a 1 per cent solution of hydrochloric acid (p. 441). *Condiments* have little direct effect, but act indirectly in adding flavour to the food, stimulating the taste buds and thus encouraging the psychic secretion. *Histamine* is one of the most powerful stimulants of gastric secretion (p. 442). Histamine liberated within the body e.g. in dermographism (p. 268) or even by the immersion of the hand in cold water at a temperature of 10°C. causes a detectable secretory response within 15 minutes. *Liver extract* (used in treatment of pernicious anemia) is also a powerful secretory excitant. *Insulin* (through its hypoglycemic effect on the vagus center), *acetylcholine* (usually), *mecholyl* (*acetyl-β-methylcholine chloride*), *pilocarpine* and *nicotine* are secretory stimulants, while *atropine* is a depressant. Atropine does not, however, inhibit the secretagogue action of alcohol and only partially prevents the effect of histamine. *Smoking* causes an increase in gastric acidity which is not due, entirely at any rate, to nicotine. *Morphine* after a brief period of inhibition stimulates gastric secretion.

THE EFFECTS OF OPERATIVE PROCEDURES UPON GASTRIC SECRETION

In dogs, partial gastrectomy (excision of the pylorus and anastomosis of the gastric stump to the duodenum) is followed by a pronounced reduction in the *quantity* of juice secreted by the fundic glands but no change occurs in the *concentration* of acid. The total acid secretion is, therefore, reduced to $\frac{1}{2}$ or $\frac{1}{3}$, (see Wilhelmji and associates). Mucous secretion is increased, and combining with the acid thus further reduces the free acid concentration of the gastric contents. Partial gastrectomy, accompanied by section of the gastric vagi, results in a profound reduction in acid secretion in response to a test meal; histamine, however, still causes a well-marked secretion.

Transplantation of a section of jejunum, with its blood supply intact, into the wall of the stomach has been shown by Stefko and his colleagues to result in a reduction of the free and combined gastric acidity during fasting and to reverse the response to histamine.

ANALYSIS OF THE STOMACH CONTENTS—TOTAL ACIDITY—FREE ACIDITY

During digestion the hydrochloric acid in the stomach exists in two forms—a smaller part combined with the protein of the food, regurgitated duodenal secretions and mucous—*combined acid* and a much larger part present in the free state—*free acid*. The sum of these

two, together with acid salts and any organic acids lactic etc. that may be present, is termed the *total acidity*. Meat and other protein-rich foods are more capable of combining with hydrochloric acid than are carbohydrates. When the hydrochloric acid is absent or falls to a low level organic acids, as a result of the fermentative processes, tend to be formed.

Samples of gastric contents are obtained for analysis by means of a Rehfuß tube. This is made of narrow flexible tubing fitted at one end with a metal tip possessing large perforations. The subject is instructed to swallow the tube slowly. To its upper end a syringe is attached, and by means of this the stomach contents are aspirated. This is done the first thing in the morning before food or drink has been taken. The healthy resting stomach secretes continuously and the fluid removed at this time (*residual juice*) under normal conditions amounts on the average to 50 cc. The total acidity of such a sample normally averages 30 units and the free acidity 20 units (see below). After the removal of the residual juice the gastric glands are excited to secrete by the ingestion of a *standard test meal*. Ewald's test meal is frequently employed and consists of two ordinary slices of toast (35 grams) and 8 ounces (250 cc.) of weak tea without milk. Others give a pint of thin gruel (Boas meal). Dilute alcohol (50 cc. of a 7 per cent solution) or an injection of histamine is also employed for stimulating gastric secretion. When the test meal is used a specimen of gastric contents (10 to 15 cc.) is removed 15 minutes after the meal has been swallowed, and during the succeeding 2½ hours at 15 minute intervals. Finally, the gastric contents are completely removed. Determinations of the free and the total acid are then made upon each sample and the corresponding acidity curves constructed (pp. 439, 440). The tube remains in position throughout the test. It was at one time the custom to make a single analysis 1 hour after the meal and to draw conclusions concerning gastric function from the results of this. But, since the acidity is continually changing, the construction of a curve from the results of analyses made at short intervals is the only logical procedure. This is known as the *fractional method of gastric analysis*, and was introduced by Rehfuß and his collaborators.

Chemical tests

QUALITATIVE. (a) *Free hydrochloric acid*. A drop of Topfer's reagent which consists of a 0.5 per cent solution of dimethyl-amino-azo-benzol is added to a cubic centimeter or so of the gastric contents. This reagent gives a red color at a pH below 3.0, that is in the presence of free HCl. It is not quite specific for it may react to high concentrations of organic acids. Gunsberg's test is more delicate and is quite specific for free HCl, giving no color change whatever with organic acids. Two drops of the reagent (1 gm. vanillin and 2 gm. phloroglucin in 30 cc. of 95 per cent alcohol) are added to 5 cc. of filtered gastric contents

in a porcelain dish. The mixture is heated over a flame with care to avoid charring. A red or orange discoloration at the drying margin of the solution is taken to indicate the presence of free HCl.

(b) *Lactic acid*. When free HCl is absent from the gastric contents (anacidity, p. 740) fermentation is likely to occur with the production of organic acids, particularly lactic. The latter is detected by means of Kelling's test—a modification of Uffelmann's. Two drops of 10 per cent ferric chloride are added to a test-tube full of distilled water. The solution is divided between two test-tubes in equal portions. A few drops of filtered gastric contents are added to one tube; a lemon yellow color appears if lactic acid is present. The solution in the other test-tube serves as a standard for comparison. The gastric contents may contain other substances which give the test and, for this reason, it is preferable to take up the lactic acid with ether, evaporate to dryness and dissolve the residue in water. The test is then applied to the aqueous solution.

QUANTITATIVE. (a) *Free hydrochloric acid*. Five cc. of strained gastric contents are diluted with 25 cc. of distilled water. Three drops of Topfer's solution are added as an indicator. The sample is then titrated with N/10 NaOH to pH 2.8 as indicated by a salmon-pink color.

(b) *Total acidity*. After noting the reading of the burette and estimating the free acid, three drops of phenolphthalein solution are added to the specimen and the titration with sodium hydroxide continued until the solution turns a definite pink.

In precise experimental work, Hollander recommends the use of bromphenol blue as indicator for free acidity, the titration being carried to pH 3.5, and phenol red for the total acidity, the end point being at pH 7.

The results of these determinations are expressed in "clinical units" i.e., the number of cubic centimeters of decinormal sodium hydroxide solution which would be required to bring 100 cc. of stomach contents to the end-point in each case (the actual figures for the free and total acid are multiplied by 20, since the volume of the specimen was 5 cc.). The total quantity of alkali required gives the value for the total acid; the first titration gives the free acid. The *percentage* of free HCl is obtained by multiplying the number of cubic centimeters of alkali required for neutralization by the factor 0.00365 (see graph, fig. 188).

(c) *Combined hydrochloric acid*. The difference between the value for the total acid and that for the free acid ($b - a$) gives the value of the combined acid plus that of any organic acids which may be present.

Estimation of peptic power

The earliest method of determining the peptic activity of a sample of gastric juice is that introduced by Mett in 1889. Egg white is drawn into a glass tube of 1 mm. bore and a few inches long. The albumin is coagulated by placing the tubes in water at a temperature of 85°C. and leaving them there until the

water has cooled. The tube is then broken into sections about an inch long, two or three of which are immersed in the gastric juice diluted 1 to 15 with N/20 HCl and incubated at a temperature of 37°C. for 24 hours. After this time the length of the column of digested albumin at each end of the tubes is measured in millimeters under the low power of the microscope and the average of a number of measurements taken. The peptic power of the sample is expressed in accordance with Schutz's law which states that the amount of proteolytic enzyme present is proportional to the square of the number of millimeters of digested albumin. Therefore, if the average length of the digested columns is 2.5 mm. the peptic power of the undiluted juice will be $2.5^2 \times 16 = 100.0$. This is the average normal value.

In the Gilman and Cowgill method, as modified by Gates, the peptic activity is determined from the rate at which the gelatin coating on a piece of photographic film is digested. The reduction in the opacity of the film is compared with a standard. Anson's method utilizes hemoglobin as the substrate. After the juice has acted upon the hemoglobin for 10 minutes, the undigested protein is precipitated with trichloroacetic acid and removed by filtration. The quantity of protein split products, which is a measure of peptic activity, is estimated colorimetrically after the addition of phenol reagent.

Determination of gastric secretory function

It is becoming more and more evident that the methods of gastric analysis as carried out in the time-honored fashion are inadequate as a means of gaining knowledge of the secretory activity of the stomach. They measure the acidity of the gastric contents and, therefore, frequently give false information or equivocal results concerning *secretion*. The acidity of the gastric contents removed after a test meal depends not only upon the secretion by the gastric glands but also upon the degree to which the secretions have been diluted by the fluids of the test meal still remaining in the stomach. It is not possible to know how much of the meal has left the stomach by the time the samples are withdrawn, unless there be added to it some soluble substance which is neither absorbed nor destroyed in the stomach and can be easily detected. Phenol red may be used for this purpose. The proportion of the gastric contents which has been secreted can then be determined and by dividing the value for the total acidity by the volume of the secretions, the acid concentration of the gastric juice itself (which contains a variable proportion of mucin) can be estimated. Furthermore, since the acid concentration of the parietal cell secretion is constant, it is possible to determine the proportions of acid and non-acid secretions in the juice.

The test meal of bread or toast and tea usually employed is unappetizing and too weak a stimulus to all phases of gastric secretion nor can alcohol or histamine rightly be considered a normal physiological

secretagogue. Liebig's test meal, consisting of a 2 per cent solution of Liebig's meat extract, contains potent and physiological secretagogues and is probably the nearest approach to the ideal test meal. The histamine test (p. 442) is valuable as a means of distinguishing true from false anacidity.

THE ISO-SECRETORY OR NORMAL CURVES OF GASTRIC ACIDITY

If in a normal person the free and total acidities of the gastric contents be determined every 15 minutes for a period of from two to three hours after the ingestion of a test meal, and the results plotted with time along the base line and HCl percentages in the vertical axis, a curve is obtained as

the great bulk of normal persons; but the gastric acidities show very wide individual variations in health, being influenced markedly by age and sex. The average free and total acidities (after a test meal) in young healthy males are about 40 and 65, respectively (see figs. 189 and 190). They are somewhat lower in females. They are also lower in children, the adult level being reached at about the age of 20 years. In men after 30 years and in women after 50 years a progressive decline in acidities (total and free) occurs and the incidence of anacidity and of subacidity (p. 442) increases sharply. A high normal value for gastric acidity is regarded by some as an index of physical fitness.

FIG. 188. Normal curves of gastric acidity following a test meal. (Redrawn from Maclean.)
FIG. 189. Normal standards. The shaded areas represent the limits within which lay 80 per cent of the data for free and total acid at the different ages. The heavy lines represent modes. (After Vanzant, Alvarez and associates.)

shown in figure 188. The curve for total acidity commences to rise a short time after the meal, and about 1 hour later reaches a maximum which varies from 35 to 70 in different persons. The curve maintains its maximal height for half an hour or less and then commences to decline reaching the resting level again in from 2 1/2 to 3 hours after the ingestion of the test meal. The curve of free acidity runs parallel to, but at a lower level than that for the total acidity, the values ranging in different normal persons between 20 and 40 (0.07 to 0.15 per cent). Values are much higher after foods, such as meats, which stimulate gastric secretion more powerfully, averaging from 80 to 120 for total and from 60 to 100 for free acidity.

The figures given above represent the range of

the level tending to be low, it is said, in persons of sedentary habits and poor muscular development.

THE REGULATION OF THE ACIDITY OF THE GASTRIC CONTENTS

The normal acidity curves, as we have seen, reach their maxima in about an hour and then commence to decline. The fall in the acidity of the gastric contents has been attributed by various authors to the following factors.

- (1) Reduction in the concentration of acid in the gastric juice.
- (2) Reduction in the total volume of juice as a result of the cessation of the psychic stimulation and gradual reduction in the secretagogue action

of the food as gastric and intestinal phases subside.

(3) Evacuation of the stomach.

(4) Reduction in free acidity of the gastric contents by saliva, food derivatives and by the alkaline mucous secretion of the pyloric portion of the stomach.

(5) Neutralization of the juice by the regurgitation of alkaline duodenal fluids—especially pancreatic juice—into the stomach.

With regard to the first factor, some authors (Rosemann, and Maclean and Griffiths) have thought that the fundic glands could secrete chloride ions in combination either with Na or H ions, i.e., as NaCl or HCl, the proportions of acid and of neutral chloride in the juice being determined by the H ion concentration of the gastric contents, a rise in their acidity causing automatically a larger proportion of chlorine to be secreted as the neutral salt. Bolton and Goodhart failed

secretion. The cephalic phase remains unaffected by acid either in the stomach or duodenum. The inhibitory effect of acid appears to be mediated through a nervous mechanism rather than by a blood-borne agent.

The termination of the cephalic phase and the progressive weakening of the gastric and intestinal phases, as the food is evacuated from the stomach and absorbed from the intestine, are important factors in the decline of gastric acidity.

Regurgitation of fluids from the duodenum has been considered an important contributory element in lessening acidity. The importance of this latter factor is, however, very questionable. That duodenal regurgitation occurs is an undoubted fact as is evidenced by the appearance of bile and trypsin in the stomach, especially in the later stages of digestion. Boldyreff in 1907 was the first to give duodenal regurgitation a prominent rôle in the regulation of gastric acidity. This observer maintained that normally a high acidity of the chyme issuing from the pylorus stimulated the secretion of pancreatic juice and set up antiperistalsis in the duodenum which carried the alkaline fluid into the stomach. The following observations, however, seem to show that duodenal regurgitation is a non-essential part of the mechanism controlling gastric acidity.

(a) Baird, Campbell and Hern observed in human subjects that the usual fall in gastric acidity occurred though the reflux of fluid from the duodenum into the stomach was prevented (duodenal contents removed by duodenal tube).

(b) McCann prevented regurgitation in dogs by separating the duodenum from the stomach and jejunum, and draining it into the lower part of the ileum. The stomach was then joined to the jejunum. The acidity curves of these animals did not differ from those of normal animals.

(c) Gastric acidity curves of isolated gastric pouches in dogs are essentially the same as those obtained from the intact human stomach.

(d) Shay, Katz and Schloss found that alkaline fluids introduced into the stomach caused a greater reflux from the duodenum than did strong acids. Water and weak acids were as effective as strong acids. These authors also pointed out that normally the juices secreted into the duodenum have a pH of around 7.2 or lower, and consequently, are not sufficiently alkaline to exert, in the quantities which are regurgitated, an important effect upon gastric acidity.

FIG. 190. Percentage decline of mean gastric acidity with advancing years (males). (After Polland.)

to obtain evidence in support of this view. They conclude that the main gastric factors bringing about the fall in acidity are, reduction in the quantity of the juice secreted by the fundic glands and evacuation of the stomach. Neutralization of the contents by the secretion of mucus was found to exert a minor effect, and only at a time when the secretion of juice was already greatly diminished. The original view of Pavlov that the acidity of the gastric juice as secreted by the glands remains constant has been confirmed by Hollander and is now widely accepted. It is apparently only the volume of the parietal secretion which varies. A rise in the acidity of the gastric contents automatically reduces the quantity of juice produced during the gastric phase of secretion. A high acidity in the duodenum also inhibits both the gastric and intestinal phases of

THE HISTAMINE TEST

As a test of gastric secretion the parenteral administration of histamine although not a normal stimulus has certain very definite advantages over the ordinary test meal: (a) Histamine evokes a maximum secretory response and is often able to evoke a response when the test meal fails to do so (see below). It is thus of value in distinguishing false from true acidity. (b) The response is not affected by conditions such as appetite and other psychic factors which influence the response to

FIG. 191. Analysis of gastric contents at 15 min. intervals after a test meal. T.C., total chlorides; I.C., inorganic chlorides; Act.HCl., "active" hydrochloric acid (i.e., difference between total and inorganic chlorides). (After Bolton, slightly modified.)

the test meal. (c) The test meal and salivary secretion, which latter cannot be measured, add to the volume of the contents; it is therefore impossible to determine accurately the quantity of juice secreted. (d) Swallowed saliva and the test meal itself partly neutralize the acid. (e) In the histamine test the glands respond promptly, maximal acidity being reached within 20 or 30 minutes; so practically pure juice is obtained for analysis, neutralization factors and gastric evacuation exert a minimum influence. The test is usually performed the first thing in the morning with the subject fasting. In a subject of average weight about 0.25 mg. is injected.

HYPOCHLORHYDRIA (SUBACIDITY) AND ANCHLORHYDRIA (ANACIDITY)

When the stomach contents give values persistently below 20 "clinical units" (0.05 per cent for free HCl after test meals, the condition is spoken of as *hypochlorhydria* or *subacidity*. The complete absence of free HCl is referred to as *achlorhydria* or *anacidity*. Bennett and Ryle in a study of 100 healthy male subjects (medical students) found achlorhydria present in 4.0 per cent. In the general run of hospital cases without gastric disease or pernicious anemia 14 to 20 per cent show anacidity. It has already been pointed out that the absence of free hydrochloric acid from

FIG. 192. Curves showing the relation between the incidence of achlorhydria and age. (After Vanzant Alvarez, and associates.)

the stomach contents may be simply the result of excessive neutralization, and not of the suppression of acid secretion. Again, there may be no secretion of acid after a test meal yet the glands respond to the more powerful stimulus of histamine: anacidity of this character is called *false* or *apparent anacidity*. The failure of acid to appear after the injection of histamine is referred to as *true anacidity*. The figures given above as reported by Bennett and Ryle for anacidity in healthy subjects as well as those given for hospital cases do not permit a distinction to be drawn between the two types of the condition, since test meals were used in the investigations. It is therefore impossible to say in what proportion of the cases true anacidity existed. The incidence of

true anacidity appears, however, to be less than 1 per cent in young healthy male subjects and not more than 1 or 2 per cent in the case of young healthy females.

In cases of anacidity the peptic concentration of the gastric juice through usually low is in some cases not far below the normal value—further evidence that the secretion of acid and of pepsin are governed by independent mechanisms. Complete absence of both acid and pepsin from the gastric contents is called *achylia gastrica*.

The incidence of anacidity, both apparent and true, shows a definite increase with advancing years up to the sixth decade. Alvarez, Vanzant and associates, in an investigation of a large series of patients without gastric disease, found it present in from 25 to 35 per cent between the ages of 60 and 70 years. Females showed a higher incidence than males. After the sixth decade some reduction in the frequency of the condition was observed (see figs. 189 and 192).

Anacidity in the majority of instances gives rise to no gastric symptoms and is compatible with perfect health. In some cases it is associated with flatulent dyspepsia and occasionally a persistent diarrhea (gastrogenous diarrhea) which is relieved by the administration of acid.

The following are the chief pathological conditions associated with anacidity;

(a) *Pernicious anemia*. Achlorhydria is a constant phenomenon (p. 64). Pepsin is also usually absent. Histamine is ineffective.

(b) *Carcinoma of the stomach*. There is anacidity in over 60 per cent of cases. It is due, according to Hurst, to the chronic gastritis which precedes and accompanies the growth. The anacidity may be either false or true.

(c) *Chronic gastritis* causes a gradual depression of the secretory function and may lead finally to its complete suppression.

(d) Hypochlorhydria or achlorhydria may also occur during *acute fevers*, in *malnutrition*, *gall-bladder disease*, *Addison's disease*, *sprue*, *acne rosacea* and *chronic arthritis*.

HYPERCHLORHYDRIA (OR HYPERACIDITY)

Hyperchlorhydria is also of common occurrence. About 5 per cent of healthy persons show the condition.

The free acid has a value of from 60 to 90 after a standard test meal, and may, instead of declining in the second hour, remain high or continue to rise. The high acidity of the gastric contents does

not mean that the juice as secreted by the gastric glands is excessively acid. So far as is known the normal maximum of from 0.5 to 0.6 per cent of hydrochloric acid in the gastric secretion is never exceeded. The high acidity of the gastric contents is due either to the secretion of an abnormally large quantity of juice (hypersecretion) or to impairment of the factors regulating gastric acidity (p. 440), e.g., failure of the secretion rate to become reduced during the second hour, or delayed gastric evacuation.

Two pathological conditions are almost invariably accompanied by hyperacidity, namely, *duodenal ulcer* (p. 444) and *pyloric obstruction* (non-malignant). In the latter condition secretions and food materials accumulate in the stomach. The gastric contents are in consequence greatly increased, the stomach becomes dilated and large quantities of fluid are vomited from time to time. The loss of acid through vomiting may result in a condition of alkalosis accompanied by tetany (p. 701). The gastric distention occurring in this condition probably serves as a stimulus to secretion (p. 433).

The neutralization test. This test is of value in investigating the acid-regulating mechanism in duodenal ulcer especially in determining the success or otherwise of an operation performed for its cure. Instead of stimulating gastric secretion by a test meal or histamine injection, 300 cc. of 0.5 per cent hydrochloric acid solution are introduced through a rubber tube, into the fasting stomach after its contents have been removed by aspiration. Samples of the acid solution are withdrawn from time to time as in the ordinary method of fractional gastric analysis, and the total acidities determined. The results are plotted and the curve compared with a normal standard curve. In the normal subject the total acidity falls from a value of 130 at the beginning of the test to around 40 within an hour or so. In cases of duodenal ulcer the total acidity falls more slowly and may be 70 or more after the lapse of 3 or 4 hours.

CHRONIC GASTRIC AND DUODENAL ULCER (PEPTIC ULCER)

Epigastric pain coming on usually in from a half to one and a half hours after a meal and vomiting are the chief clinical features of gastric ulcer. In a certain proportion (about 20 per cent) of cases blood appears in the vomitus (hematemesis).

In duodenal ulcer, pain occurs usually within from two to three hours after a meal, that is, when

the stomach is nearly empty. The onset of the pain is therefore earlier after a light than after a heavy meal. The pain is relieved by taking food.

Pathogenesis

It is generally agreed that the dominant factor in the development of gastric and of duodenal ulcer is the action of the pepsin-hydrochloric acid of the gastric juice. The term peptic ulcer is therefore well chosen. The importance of this factor is evidenced by the following facts.

(1) Apart from the ulcerations caused by some specific disease, e.g., tuberculosis, syphilis, carcinoma, etc., ulcer of the gastro-intestinal tract is confined to those regions which are exposed to the action of acid. (a) Gastric ulcers in the great majority of cases involve the pyloric part of the stomach; they are most frequently situated on the lesser curvature near the incisura angularis or on the anterior or posterior wall in close proximity to this limited area. They are never seen in the dome of the fundus and rarely on the upper part of the greater curvature; these regions, it will be noted, are not in contact with acid for any length of time. (b) The lower part of the esophagus into which highly acid juice frequently regurgitates, and the adjacent part of the stomach wall, i.e., the cardia, are sometimes the site of ulceration. (c) Duodenal ulcer occurs practically exclusively within the first inch or less of the duodenal cap (p. 490), and nearly always upon its anterior or posterior wall, that is, where the chyme before it has been neutralized by the alkaline juices of the duodenum comes into contact with the mucosa. (d) After gastrojejunostomy, the so-called *stomal ulcer* may occur in the jejunal mucosa in the region of the anastomosis, i.e., where the gastric juice first impinges. (e) In a Meckel's diverticulum which contains ectopic gastric glands an ulcer occasionally forms. The ulcer's site is either in that part of the mucosa of the diverticulum which does not itself contain acid-secreting glands, or in the ileum at the point where the diverticulum opens into it. Matthews and Dragstedt, experimenting with dogs, produced an "artificial Meckel's diverticulum" by transplanting a pouch of the gastric wall into the ileum; an ulcer developed in the ileum just beyond the transplant in every experiment. These observations emphasize a curious fact that the commonest situations of ulcer are not in the mucosa which itself secretes the acid, but in neighboring parts which normally secrete a neutral or alkaline fluid—the pyloric region, duodenal cap, cardiac region, esophagus, jejunum

or ileum. The pyloric type of gland extends farther up the lesser than up the greater curvature (fig. 193). It has even been suggested that the occurrence of ulcers in the body of the stomach, i.e., in the acid secreting part of the mucosa, is actually dependent upon the presence of patches of aberrant pyloric glands. (f) Mann and Williamson, employing dogs, excised the duodenum and transplanted it into the ileum, thus diverting its alkaline juices away from the region of the pylorus. The cut end of the jejunum was anastomosed to the pylorus. Fourteen out of sixteen animals upon which this operation was performed developed chronic ulcers in the jejunum just beyond the pylorus. However, Fawley and Ivy found that this operation, if combined with excision of the

FIG. 193. Diagram showing the distribution of the parietal (acid-secreting) cells in the human stomach. In the black area the proportion of parietal cells was maximal and was taken as 100 per cent; in the cross-hatched area on lesser curvature the percentage of parietal cells was 75 per cent, in the shaded area at the fundus, 50 per cent, and in the white area 0 to 1 per cent. (After Berger, *Amer. J. Anat.*, 1934, 54, 87.)

fundus, or if the alkaline secretions are drained into the stomach, does not cause a jejunal ulcer.

(2) In a very large proportion of subjects of duodenal ulcer the concentration of free hydrochloric acid in the gastric contents after a test meal is abnormally high. The interdigestive or basal secretion is increased much above the normal; the pepsin concentration of the secretion is also frequently increased. According to Hurst, hyperchlorhydria (p. 443) is present in 61 per cent of cases. Of the remainder the majority show an acidity which is near the higher limit of the normal, a few have subacidity, but true achlorhydria is almost never seen. Gastric or duodenal ulcer occurs very rarely, if ever, in subjects of pernicious anemia in which gastric anacidity is almost invariable. The typical findings upon gastric analysis are: a fasting juice of greater volume than normal and of high acidity; and a

curve of gastric acidity after a test meal which rises well above (20 units or more) the normal maximum. In some cases the stomach empties more rapidly than usual as a result of exaggerated gastric motility and the curve of acidity after reaching its maximum value falls steeply again. In other instances the stomach empties in the usual time but the curve of acidity is maintained at its maximum as a result of continued gastric secretion—the *plateau type of curve*. In still other instances the emptying of the stomach is delayed as a result of pylorospasm or achalasia (see below), and the curve of gastric acidity instead of falling at the usual time continues to rise—the so-called *climbing curve* (fig. 194). High gastric acidity is less commonly associated with

with acid alone will not cause ulceration but this is readily produced by the addition of pepsin to the perfusion fluid.

(4) Measures directed toward the prevention of excessive gastric secretion and toward the neutralization of the acidity of the gastric contents are of outstanding value in encouraging the healing of the ulcer (p. 448).

Though the importance of acid in the production of ulcer cannot be denied this factor cannot be solely concerned. For one thing, many persons who show hyperchlorhydria do not develop ulcer. "Why in these instances is the gastric mucosa immune to the action of the pepsin-hydrochloric acid?" Indeed, the question has often been asked, "Why does not the pepsin-hydro-

FIG. 194. Chart showing "climbing" type of curve of gastric acidity. (After Ryle.)

gastric ulcer; according to Vanzant the acidity is actually a little below the normal average. True anacidity, however, is rarely, if ever, found. The relatively low gastric acidities found in gastric ulcer are probably the result of an associated gastritis and do not necessarily indicate that hyperchlorhydria did not precede the development of the ulcer.

(3) Stimulation of gastric secretion, as by the continued administration of histamine or of caffeine (p. 447), is one of the most effective experimental means of producing gastric ulcer. Although gastric ulcers are produced experimentally by means of a constant drip over the gastric mucosa of a solution of hydrochloric acid, some pepsin must have been furnished by the stomach itself. Irrigation of a loop of jejunum

chloric acid of even normal gastric juice digest the gastric or duodenal mucosa?" It is also an extraordinary fact, firmly established by several workers, that the tissue of other parts of the intestinal tract or of other organs, though susceptible to the action of acid in their normal situations, are not digested when transplanted into the wall of the stomach. Dragstedt and Vaughn, for example, removed areas from the gastric wall of dogs and then sutured portions of the duodenum, ileum, jejunum, colon, spleen or kidney into the gaps. In no case was the transplanted tissue digested (see also p. 438). In the case of the kidney and spleen their gastric surfaces became covered with a layer of gastric epithelium. Sections of transplanted intestinal mucosa were found

to be perfectly normal after a period of nine months.

On the other hand, as shown years ago by Claude Bernard, the intact leg of a living frog is digested when introduced through a fistula into the stomach of a dog. Pavy showed the same thing for the rabbit's ear and Dragstedt and Vaughn have demonstrated that the intact limb of a live frog placed in an extract of frog's gastric mucosa is digested.

There is no satisfactory answer to the question of why the stomach does not digest its own wall. One explanation offered was that the greater alkalinity of the blood coursing through the vessels of the gastric tubules as a result of the loss of Cl ions served to neutralize the effect of the acid juice. Others have suggested that the immunity of the gastric mucosa to autodigestion is due to its containing an antipepsin. Another suggestion is that the mucin which coats the mucosa exerts a protective action.

A very interesting observation which may have a bearing upon the question has been reported by Mann and Bollman. They instilled a 0.4 per cent solution of hydrochloric acid into the stomach of dogs continuously (at the rate of 1 cc. per minute) for 8 hours daily. After a month of this treatment an ulcer formed in the region of the lesser curvature. If, however, the animal had been fed some time before the commencement of each experiment, and the remnants of food then washed away, the stomach was found to have become resistant to the action of the acid. Indeed, the acid was rapidly neutralized. Peptones appear to be responsible for the protective action displayed. The preventive action of proteins (casein, gelatin, edestin) upon ulcer development has also been demonstrated by Matzner and others.

A CONSIDERATION OF OTHER FACTORS CONCERNED IN THE PRODUCTION OF ULCER. *Bacterial infection*, and interference with the *blood supply* to the mucosa, either as a result of emboli or thrombosis have been thought by some to be responsible for ulcer production. Except perhaps in rare instances, these are no longer believed to play a rôle. *Tobacco smoking* probably through its action in stimulating gastric secretion appears, in some instances at any rate, to encourage ulcer formation or to interfere with the healing of an ulcer already formed. *Trauma*, although not essential to the production of ulcer is probably often a contributory factor. It is not difficult to believe that in the presence of other causative factors,

rubbing of food against the gastric mucosa or the passage of coarse indigestible material into the duodenal cap, will encourage the production of ulcer, or retard the healing of one already present. It is to be remembered that food after entering the stomach passes along the lesser curvature, i.e., through the *magenstrasse* (p. 484), and, as already mentioned, this region is one of the commonest sites of gastric ulcer. Experimental erosions in this situation heal much more slowly than do those produced along the greater curvature. Mann and Bollman also point out that the site of duodenal ulcer corresponds to the area of mucosa upon which the gastric contents impinge, and, when the gastric movements are energetic, this may occur with considerable force. They found that the experimental production of ulcer was considerably delayed if the propulsive force of the stomach was reduced by making an hour-glass constriction in the pre-pyloric region. Ivy and his associates have also shown that in the rabbit coarse food retards the healing of an area of the stomach wall from which the mucosa has been excised.

The neurogenic element in the production of ulcer

Cushing was the first within recent years to stress the importance of nervous influences in the pathogenesis of ulcer. He drew attention to the relatively high incidence of acute gastric ulcers after intracranial operations. Others previously had remarked upon the association of tumors of the mid-brain and diencephalon with gastric or duodenal ulcers, and the older pathologists had mentioned the frequency of softening of the gastric wall (gastromalacia) and other gastric lesions in subjects dying of cerebral conditions. Cushing suggests that the influences arising in the parasympathetic center in the hypothalamus (p. 883) and conveyed along the vagus nerves, are responsible for changes in the gastric mucosa which lead to the development of ulcer.

The experimental investigations of a number of workers support this conception. Beattie, for example, produced areas of hyperemia and small erosions in the gastric mucosa (lesser curvature) for stimulation of the hypothalamus in the region of the tuber cinereum. Keller and his associates have observed ulcerations of the stomach and proximal duodenum with small hemorrhages, following lesions of the hypothalamus. Hyperemia and erosions of the gastric mucosa have also been produced by the injection of pilocarpine (a parasympathetic stimulant) into the third ventricle or by continued stimulation of the vagus nerve.

It may also be recalled that stimulation of the hypothalamus in the region of the tuber cinereum is followed by movements of the stomach (p. 484), and that hypersecretion and gastric hypertonus (steer-horn type of stomach) are prominent features of duodenal ulcer. Moreover, it is recognized that the nervous "highly strung" type of person is more likely to be the subject of ulcer than is the phlegmatic type, and that an ulcer in the process of healing not uncommonly relapses as a result of some nervous influence, worry, emotional shock, etc. Babkin suggests the possibility that vagal impulses cause the liberation of histamine in the gastric mucosa. Through its vasodilator action and stimulating effect upon the parietal cells, conditions favorable to ulcer production are provided, namely, high gastric acidity and, through capillary stasis, defective blood supply to the mucous membrane.

The experimental production of gastric ulcer. Besides the methods already mentioned, namely, by diverting the alkaline secretion into the ileum and stimulation of the hypothalamic region, gastric ulceration can be produced in animals by the daily oral administration of *cinchophen* or by the injection of *pitressin*. Gastric ulcers can also be produced by the continued action of *histamine* or *caffeine*. They are administered intramuscularly in beeswax in order to prolong their stimulating effect upon gastric secretion. The mode of action of *cinchophen* (which also in large doses causes liver damage) is unknown. *Pitressin* (or *pituitrin*) apparently induces superficial necrosis of the mucosa as a result of vascular spasm (see Dodds and associates). Byrom has shown that following *pituitrin* administration necrotic areas accompanied by small hemorrhages occur in other organs as well.

The cause of the pain in duodenal ulcer
